Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Contents

Preface to the fourth edition	ix
List of Contributors	xi
SECTION A: Basic principles and investigations	
1. Surgical anatomy <i>Adrian Lower</i>	1
2. Hysteroscopy <i>Nazar N. Amso, Richard J. Penketh and Asmita Patwardhan</i>	17
3. Laparoscopy <i>Alan Farthing and Alexandra Lawrence</i>	36
4. Diathermy and lasers <i>Priya Agrawal and Fiona Reid</i>	48
5. Imaging techniques in gynaecology <i>Nandita deSouza and David Cosgrove</i>	59
6. One-stop gynaecology: the role of ultrasound in the acute gynaecological patient <i>Kevin Jones and Tom Bourne</i>	80
7. Preoperative care <i>Kate P. Stewart and Saad A. Amer</i>	93
8. Principles of surgery and management of intra-operative complications <i>Angus McIndoe</i>	105
9. Postoperative care <i>Saad A. Amer</i>	116
10. Hormones: their action and measurement in gynaecological practice <i>Scott McGill Nelson and Jurgis Gedis Grudzinskas</i>	128
11. Biosynthesis of steroid hormones <i>Anthony E. Michael and Robert Abayasekara</i>	145
12. Principles and new developments in molecular biology <i>Raheela Khan</i>	156
SECTION B: Reproductive medicine	
13. Sexual differentiation — normal and abnormal <i>D. Keith Edmonds</i>	166
14. Disorders of puberty <i>Adam Balen</i>	182
15. Control of hypothalamic-pituitary-ovarian function <i>Robert W. Shaw</i>	197
16. Amenorrhoea, oligomenorrhoea and hypothalamic-pituitary dysfunction <i>Hilary O.D. Critchley, Andrew Horne and Kirsty Munro</i>	212

17. Ovulation induction	231
<i>Maria Vogiatzi and Robert W. Shaw</i>	
18. Polycystic ovary syndrome	251
<i>Adam Balen</i>	
19. Fertilization and implantation	265
<i>Hayden Homer and Alison Murdoch</i>	
20. Disorders and investigation of female reproduction	278
<i>Mark Hamilton</i>	
21. Disorders of male reproduction	292
<i>Richard A. Anderson and D. Stewart Irvine</i>	
22. Assisted reproduction treatments	312
<i>Kannamannadiar Jayaprakasan and James Hopkisson</i>	
23. Sporadic and recurrent miscarriage	335
<i>William M. Buckett and Lesley Regan</i>	
24. Tubal disease	353
<i>Ertan Saridogan, Essam El Mahdi and Ovrang Djahanbakhch</i>	
25. Ectopic pregnancy	363
<i>Neelam Potdar and Justin C. Konje</i>	
26. Hirsutism and virilisation	382
<i>Julian Barth</i>	
27. Premenstrual syndrome	391
<i>Sungathi Chandru, Radha Indusekhar and P.M. Shaughn O'Brien</i>	
28. Menopause	405
<i>Margaret Rees</i>	
29. Fertility control	422
<i>Catherine A. Schünmann and Anna F. Glasier</i>	
30. Psychosexual medicine	440
<i>Susan V. Carr</i>	
31. Menstruation and menstrual disorders	448
<i>Sujan Sen and Mary Ann Lumsden</i>	
32. Uterine fibroids	473
<i>Gareth Weston and David L. Healy</i>	
33. Endometriosis	488
<i>Robert W. Shaw</i>	

SECTION C: Benign and malignant tumours

34. Epidemiology of gynaecological cancer	509
<i>Peter Sasieni, Alejandra Casteñón and Jack Cuzick</i>	
35. The genetics and molecular biology of gynaecological cancer	522
<i>Martin Widschwendter, Simon Gayther and Ian J. Jacobs</i>	
36. Principles of radiotherapy and chemotherapy	539
<i>Nawaz Walji and Indrajit Fernando</i>	
37. Novel therapies in gynaecological cancer	554
<i>Debra Josephs, Susannah Stanway and Martin Gore</i>	
38. Premalignant diseases of the genital tract	566
<i>Esther Moss, Charles W. Redman and Raji Ganesan</i>	
39. Cancer of the uterine cervix	582
<i>Kavita Singh and Janos Balega</i>	
40. Benign disease of the vulva and the vagina	599
<i>Allan Maclean and Wendy Reid</i>	
41. Malignant disease of the vulva and the vagina	613
<i>Shing Shun N. Siu and David Luesley</i>	

42.	Malignant disease of the uterus <i>Sudha S. Sundar and Suhail Anwar</i>	629
43.	Gestational trophoblastic tumours <i>Thomas Newsom-Davis and Michael J. Seckl</i>	650
44.	Benign tumors of the ovary <i>Ulises Zanetto and Gabrielle Downey</i>	668
45.	Carcinoma of the ovary and fallopian tube <i>Sean Kehoe</i>	678
46.	Benign disease of the breast <i>Paul TR Thiruchelvam, William E. Svensson and John Lynn</i>	689
47.	Malignant disease of the breast <i>Paul TR Thiruchelvam, William E. Svensson and John Lynn</i>	707
48.	Supportive care for gynaecological cancer patients: psychological and emotional aspects <i>Karen Summerville</i>	750
 SECTION D: Urogynaecology		
49.	Classification of urogynaecological disorders <i>Stuart L. Stanton and Ash Monga</i>	767
50.	The mechanism of continence <i>Ash Monga and Abdul Sultan</i>	771
51.	Urodynamic investigations <i>Philip Tooze-Hobson and Matthew Parsons</i>	783
52.	Urethral sphincter incompetence <i>Fiona Reid and Anthony RB Smith</i>	798
53.	The overactive bladder syndrome <i>Dudley Robinson and Linda Cardozo</i>	813
54.	Voiding difficulties <i>L. Bombieri and Robert Freeman</i>	836
55.	Pelvic organ prolapse <i>Colin A. Walsh and Mark Slack</i>	849
56.	Frequency, urgency and the painful bladder <i>Michelle M. Fynes and Stergios K. Doumouchtsis</i>	864
57.	Fistulae <i>Paul Hilton</i>	874
58.	Urinary tract infection <i>Charlotte Chaliha and Michael R. Millar</i>	896
59.	Lower intestinal tract disease <i>Karen Nugent</i>	907
60.	Sexual dysfunction in urogynaecology <i>Ranee Thakar</i>	919
 SECTION E: Women's reproductive health		
61.	Chronic pelvic pain <i>William Stones</i>	929
62.	Pelvic inflammatory disease <i>Nazar N. Amso and Anthony Griffiths</i>	942
63.	Non-HIV Sexually transmitted infections <i>Daniel P. Hay and Eimear P. Kieran</i>	955
64.	Human immunodeficiency syndrome <i>Saurabh V. Phadnis and Margaret A. Johnson</i>	979

65.	Forensic gynaecology	988
	<i>Helen Margaret Cameron</i>	
66.	Violence against women	1002
	<i>Mary Hepburn and Kirstyn Brogan</i>	
67.	Lesbian and bisexual women's health issues	1009
	<i>Julie Fish and Susan Bewley</i>	
68.	Evidence-based care in gynaecology	1017
	<i>Arri Coomarasamy and Siladitya Bhattacharya</i>	
	Index	1025

Preface

to the fourth edition

This fourth edition of *Gynaecology* looks to the challenges we face in our specialty in the 21st century. Healthcare provision has changed a great deal even in the first decade of this century, and so too has this textbook to address these issues. We look to update our readers of all the major advances since the previous edition.

We have two new editors — Professor David Luesley who is overseeing the Gynaecological Oncology, Section 3, and Mr Ash Monga who edits the Urogynaecology, Section 4. Both are recognised subspecialists in their respective fields and bring, not only their personal perspectives to their sections, but also have recruited many new chapter contributors to reflect the increasing number of subspecialists being appointed in gynaecology.

Recognising the multidisciplinary nature of much of the care we now offer our patients to ensure access to other medical staff with allied expertise to our own and to improve our patients' outcomes, is reflected in contributions from many other colleagues from other medical specialities.

We have reviewed carefully previous chapter headings, content, style and length. This has meant the amalgamation of some previous chapters to reflect changing emphasis in the practice of gynaecology, the recognition of increased day case operative laparoscopic and hysteroscopic procedures. There has also been an increased role and use of medical therapies in many areas of reproductive medicine. This has opened up the field of what some may call a separate special-

ity of 'medical gynaecology'. This shift away from surgery as the prime treatment choice for many gynaecology problems has implications for future surgical training of our juniors and the realisation that many may not be undertaking major gynaecological procedures in their future careers.

The publication of the human genome in 2006 and the increased application of molecular biological techniques in research is beginning to unearth the cellular and molecular basis of many gynaecological benign and malignant conditions. However, it is early days of such work and we await the potential advances in new therapies which may come from this increased understanding of pathogenesis and for 'regenerative medicine' from stem cell work and gene therapy to become realities in terms of treatment potential.

Each chapter has been rewritten, we have many new authors and adopted a new presentation with greater use of colour illustrations. This book will serve equally well as a comprehensive text for the already established specialist in gynaecology as well as a useful source for trainees preparing for specialist examinations.

We hope that you will both find its contents useful and enjoy reading the book as much as we have enjoyed collating and editing its contents.

List of Contributors

Robert Abayasekara BSc (Hons), MA (Cantab), PhD

Senior Lecturer in Physiology
Department of Veterinary Basic Sciences
Royal Veterinary College
London, UK

Priya Agrawal MD

Specialist Registrar in
Obstetrics and Gynaecology
St Mary's Hospital
London, UK

Saad A Amer MRCOG, MSc, MD

Associate Professor and
Consultant Gynaecologist
University of Nottingham
Royal Derby Hospital
Nottingham, UK

Nazar N Amso PhD, FRCOG

Clinical Senior Lecturer
Obstetrics & Gynaecology
Cardiff University School of
Medicine
Cardiff, UK

Richard A Anderson MD, PhD, FRCOG

Professor of Clinical
Reproductive Science
Centre for Reproductive
Biology
University of Edinburgh
Edinburgh, UK

M Suhail Anwar MBBS, BSc, MRCP (UK), MRCP (Ireland), FRCP (UK)

Consultant Clinical Oncologist
The Cancer Centre
University Hospital
Birmingham NHS Foundation
Trust
Birmingham, UK

Janos Balega MD, MRCOG

Consultant Gynaecological
Oncologist
Pan-Birmingham Gynaecology
Cancer Centre
Birmingham, UK

Adam Balen MD, FRCOG

Professor of Reproductive
Medicine & Surgery
Leeds Teaching Hospitals
Leeds, UK

Julian Barth MD, FRCP, FRCPATH

Consultant in Chemical
Pathology & Metabolic
Medicine
Clinical Biochemistry
Leeds General Infirmary
Leeds, UK

Susan Bewley MD, MA, FRCOG

Consultant Obstetrician/
Maternal Fetal Medicine and
Honorary Senior Lecturer
Kings Health Partners
London, UK

Introduction

A clear understanding of the anatomy of the female pelvis is essential to successful gynaecological surgery and the avoidance of surgical morbidity. The close relationships between the reproductive, urinary and gastrointestinal tracts must be appreciated, together with the pelvic musculofascial support, vascular and lymphatic circulations, and neurological innervation. It is important to understand the effect of pneumoperitoneum on the anatomy and relationships of the pelvis, and the opportunities afforded by a retroperitoneal approach in minimal access techniques. Figure 1.1 shows a panoramic view of the pelvis from the umbilicus during a laparoscopy. The probe is lifting the right ovary, displaying the right pelvic side wall and ureter (arrows).

The Ovary

The size and appearance of the ovaries depend on both age and the stage of the menstrual cycle. In the young adult, they are almond shaped, solid and white in colour, 3 cm long, 1.5 cm wide and approximately 1 cm thick. The long axis is normally vertical before childbirth; after this, there is a wide range of variation, presumably due to considerable displacement in the first pregnancy.

The ovary is the only intra-abdominal structure not to be covered by peritoneum. Each ovary is attached to the cornu of the uterus by the ovarian ligament, and at the hilum to

the broad ligament by the mesovarium, which contains its supply of vessels and nerves. Laterally, each is attached to the suspensory ligament of the ovary with folds of peritoneum which become continuous with that over the psoas major.

Structure

The ovary has a central vascular medulla, consisting of loose connective tissue containing many elastin fibres and non-striated muscle cells, and an outer thicker cortex, denser than the medulla and consisting of networks of reticular fibres and fusiform cells, although there is no clear-cut demarcation between the two. The surface of the ovary is covered by a single layer of cuboidal cells, the germinal epithelium. Beneath this is an ill-defined layer of condensed connective tissue, the tunica albuginea, which increases in density with age. At birth, numerous primordial follicles are found, mainly in the cortex but some in the medulla. With puberty, some form each month into Graafian follicles which, at later stages of their development, form corpora lutea and ultimately atretic follicles, the corpora albicantes (Figure 1.2).

Relations

Anteriorly lie the fallopian tubes, the superior portion of the bladder and the uterovesical pouch; posteriorly is the pouch of Douglas. The broad ligament and its content are

related inferiorly, whilst superior to the ovaries are the bowel and the omentum. The lateral surface of the ovary is in contact with the parietal peritoneum and the pelvic side walls.

Vestigial structures

The vestigial remains of the mesonephric duct and tubules are always present in young children, but are variable structures in adults. The epoophoron, a series of parallel blind tubules, lies in the part of the broad ligament between the mesovarium and the fallopian tube, the mesosalpinx. The tubules run to the rudimentary duct of the epoophoron, which runs parallel to the lateral fallopian tube. A few rudimentary tubules, the paroophoron, are occasionally seen in the broad ligament, between the epoophoron and the uterus.

In a few individuals, the caudal part of the mesonephric duct is well developed, running alongside the uterus to the internal os. This is the duct of Gartner.

Age-related changes

During early fetal life, the ovaries are situated in the lumbar region near the kidneys. They gradually descend into the lesser pelvis and, during childhood, they are small and situated near the pelvic brim. They are packed with primordial follicles. The ovary grows in size until puberty by an increase in the stroma. Ova are first shed around the time of onset of menstruation, and ovulation is usually established within a couple of years.

After the menopause, the ovary atrophies and assumes a smaller, shrivelled appearance. The fully involuted ovary of old age contains practically no germinal elements.

Blood supply

The main vascular supply to the ovaries is the ovarian artery, which arises from the anterolateral aspect of the aorta just below the origin of the renal arteries. The right artery crosses the anterior surface of the vena cava, the lower part of the abdominal ureter and then, lateral to the ureter, enters the pelvis via the infundibulopelvic ligament. The left artery crosses the ureter almost immediately after its origin and then travels lateral to it, crossing the bifurcation of the common iliac artery at the pelvic brim to enter the infundibulopelvic ligament. Both arteries then divide to send branches to the ovaries through the mesovarium. Small branches pass to the ureter and the fallopian tube, and one branch passes to the cornu of the uterus where it freely anastomoses with branches of the uterine artery to produce a continuous arterial arch (see Figure 1.3).

The ovarian and uterine trunks drain into a pampiniform plexus of veins in the broad ligament near the mesovarium,

Figure 1.1 View of the pelvis with uterus anteverted from laparoscopy. Right ovary turned over with probe to expose right pelvic sidewall. FT, fallopian tube; POD, pouch of Douglas; US, uterosacral ligament.

Figure 1.2 Diagrammatic section of an ovary and schematic representation of the cycle of follicular maturation.

Figure 1.3 Posterosuperior aspect of the uterus and the broad ligament as seen from the umbilicus at laparoscopy.

which can occasionally become varicose. The right ovarian vein drains into the inferior vena cava, the left usually into the left renal vein.

The Fallopian Tube

The uterine or fallopian tubes are two oviducts originating at the cornu of the uterus which travel a rather tortuous course along the upper margins of the broad ligament. They are approximately 10 cm in length and end in the peritoneal cavity close to the ovary. This abdominal opening is situated at the end of a trumpet-shaped lateral portion of tube, the infundibulum. This opening is fringed by a number of petal-like processes, the fimbriae, which closely embrace the tubal end of the ovary. This fimbriated end has an important role in fertility.

Medial to the infundibulum is the ampulla which is thin walled and tortuous, and comprises at least half of the length of the tube. The medial third of the tube, the isthmus, is relatively straight. The tube has narrowed at this point, from approximately 3 mm at the abdominal opening to 1–2 mm. The final centimetre, the interstitial portion, is within the uterine wall.

Structure

The tubes are typical of many hollow viscera in that they contain three layers. The outer serosal layer consists of peritoneum and underlying areolar tissue. This covers the whole tube apart from the fimbriae at one end and the interstitial portion at the other. The middle muscular layer consists of outer longitudinal fibres and inner circular fibres. This is fairly thick at the isthmus and thins at the ampulla.

The mucous membrane is thrown into a series of plicae or folds, especially at the infundibular end. It is lined with columnar epithelium, much of which contains cilia which, together with the peristaltic action of the tube, help in sperm and ovum transport. Secretory cells are also present, as well as a third group of intercalary cells of uncertain function.

Relations

These are similar to those of the ovary (see above). Medially, the fallopian tube, after arching over the ovary, curves around its tubal extremity and passes down its free border.

Blood supply

The fallopian tube is supplied by branches from the vascular arcade formed by the ovarian artery laterally and a branch of the uterine artery medially.

The Uterus

The uterus is shaped like an inverted pear, tapering inferiorly to the cervix and, in the non-pregnant state, is situated entirely within the lesser pelvis. It is hollow and has thick muscular walls. Its maximal external dimensions are approximately 9 cm long, 6 cm wide and 4 cm thick. The upper expanded part of the uterus is termed the 'body' or 'corpus'. The area of insertion of each fallopian tube is termed the 'cornu' and that part of the body above the cornu, the 'fundus'. The uterus tapers to a small central constricted area, the isthmus, and below this is the cervix, which projects obliquely into the vagina and can be divided into vaginal and supravaginal portions (Figure 1.4).

The cavity of the uterus has the shape of an inverted triangle when sectioned coronally; the fallopian tubes open at the upper lateral angles (Figure 1.5). The lumen is apposed anteroposteriorly. The constriction at the isthmus where the corpus joins the cervix is the anatomical internal os.

Structure

The uterus consists of three layers: the outer serous layer (peritoneum), the middle muscular layer (myometrium) and the inner mucous layer (endometrium).

The peritoneum covers the body of the uterus and, posteriorly, the supravaginal portion of the cervix. This serous coat is intimately attached to a subserous fibrous layer, except laterally where it spreads out to form the leaves of the broad ligament.

Figure 1.4 Median sagittal section through a female pelvis.

Figure 1.5 Sectional diagram showing the interior divisions of the uterus and its continuity with the vagina.

The muscular myometrium forms the main bulk of the uterus and comprises interlacing smooth muscle fibres intermingling with areolar tissue, blood vessels, nerves and lymphatics. Externally, these are mostly longitudinal but the larger intermediate layer has interlacing longitudinal, oblique and transverse fibres. Internally, they are mainly longitudinal and circular.

The endometrium forms the inner layer and is not sharply separated from the myometrium: the tubular glands dip into the innermost muscle fibres. A single layer of columnar epi-

thelium covers the endometrium. Ciliated prior to puberty, this columnar epithelium is mainly lost due to the effects of pregnancy and menstruation. The endometrium undergoes cyclical histological changes during menstruation and varies in thickness between 1 and 5 mm.

The cervix

The cervix is cylindrical in shape, narrower than the body of the uterus and approximately 2.5 cm in length. It can be divided into the upper, supravaginal and lower vaginal portions. Due to ante flexion or retroflexion, the long axis of the cervix is rarely the same as the long axis of the body. Anterior and lateral to the supravaginal portion is cellular connective tissue, the parametrium. The posterior aspect is covered by the peritoneum of the pouch of Douglas. The ureter runs approximately 1 cm laterally to the supravaginal cervix. The vaginal portion projects into the vagina to form the fornices.

The upper part of the cervix mainly consists of involuntary muscle, whereas the lower part is mainly fibrous connective tissue.

The mucous membrane of the endocervix has anterior and posterior columns from which folds radiate out, the arbor vitae. It has numerous deep glandular follicles which secrete a clear alkaline mucus, the main component of physiological vaginal discharge. The epithelium of the endocervix is cylindrical and also ciliated in its upper two-thirds, and changes to stratified squamous epithelium around the region of the external os. This change may be abrupt or there may be a transitional zone up to 1 cm in width.

Position

The longitudinal axis of the uterus is approximately at right angles to the vagina and normally tilts forwards; this is

termed 'anteversion'. The uterus is usually also flexed forwards on itself at the isthmus; this is termed 'anteflexion'. In approximately 20% of women, this tilt is not forwards but backwards, termed 'retroversion' or 'retroflexion'. In most cases, this does not have pathological significance and the uterus is mobile.

Relations

Anteriorly, the uterus is related to the bladder and is separated from it by the uterovesical pouch of peritoneum. Posteriorly is the pouch of Douglas plus coils of small intestine, sigmoid colon and upper rectum. Laterally, the relations are the broad ligament and that contained within it. Of special importance are the uterine artery and the ureter, running close to the supravaginal cervix.

Age-related changes

The disappearance of maternal oestrogenic stimulation after birth causes the uterus to decrease in length by approximately one-third and in weight by approximately one-half. The cervix is then around twice the length of the body of the uterus. At puberty, however, the corpus grows much faster and the size ratio reverses; the body becomes twice the length of the cervix. After the menopause, the uterus undergoes atrophy, the mucosa becomes very thin, the glands almost disappear and the walls become less muscular. These changes affect the cervix more than the corpus, so the cervical lips disappear and the external os becomes more or less flush with the vault.

The Vagina

The vagina is a fibromuscular tube which extends postero-superiorly from the vestibule to the uterine cervix. It is longer in its posterior wall (approximately 9 cm) than anteriorly (approximately 7.5 cm). The vaginal walls are normally in contact, except superiorly, at the vault, where they are separated by the cervix. The vault of the vagina is divided into four fornices: posterior, anterior and two lateral. These increase in depth posteriorly. The mid-vagina is a transverse slit and the lower portion has an H-shape in transverse section.

Structure

The skin of the vagina is firmly attached to the underlying muscle and consists of stratified squamous epithelium. There are no epithelial glands present and the vagina is lubricated by mucus secretion from the cervix and Bartholin's glands. The epithelium is thick and rich in glycogen, which increases in the postovulatory phase of the cycle. Doderlein's bacillus is a normal commensal of the vagina, breaking down the glycogen to form lactic acid and producing a pH of approximately 4.5. This pH has a protective role for the vagina in decreasing the incidence of pyogenic infection.

The muscle layers consist of an outer longitudinal and inner circular layer, but these are not distinctly separate and are mostly spirally arranged and interspersed with elastic fibres.

The hymen

The hymen is a thin fold of mucous membrane across the entrance to the vagina. It has no known function. There are usually one or more openings in it to allow menses to escape. If these are not present, a haematocolpos will form with the commencement of menstruation. The hymen is usually, but not always, torn with first intercourse but can also be torn digitally or with tampons. It is certainly destroyed in childbirth and only small tags, carunculae myrtiformes, remain.

Relations

The upper posterior vaginal wall forms the anterior peritoneal reflection of the pouch of Douglas. The middle third is separated from the rectum by pelvic fascia and the lower third abuts the perineal body.

Anteriorly, the upper vagina is in direct contact with the base of the bladder, whilst the urethra runs down the lower half in the midline to open into the vestibule; its muscles fuse with the anterior vaginal wall.

Laterally, at the fornices, the vagina is related to the attachment of the cardinal ligaments. Below this are the levator ani muscles and the ischiorectal fossa. Near the vaginal orifice, the lateral relations include the vestibular bulb, bulbospongiosus muscle and Bartholin's gland.

Age-related changes

Immediately after birth, the vagina is under the influence of maternal oestrogen so the epithelium is well developed. Acidity is similar to that of an adult and Doderlein's bacilli are present. After a couple of weeks, the effects of maternal oestrogen disappear, the pH rises to 7 and the epithelium atrophies.

At puberty, the reverse occurs. The pH becomes acid again, the epithelium undergoes oestrogenization and the number of Doderlein's bacilli increases markedly. The vagina undergoes stretching during coitus, and especially childbirth, and the rugae tend to disappear.

At the menopause, the vagina tends to shrink and the epithelium atrophies.

The Vulva

The female external genitalia, commonly referred to as the 'vulva', include the mons pubis, the labia majora and minora, the vestibule, the clitoris and the greater vestibular glands (Figure 1.6).

Labia majora

The labia majora are two prominent folds of skin with underlying adipose tissue bounding either side of the vaginal opening. They contain numerous sweat and sebaceous glands, and correspond to the scrotum of the male. Anteriorly, they fuse together over the symphysis pubis to form a deposition of fat, the mons pubis. Posteriorly, they merge with the perineum. From puberty onwards, the lateral aspects of the labia majora and the mons pubis are covered

with coarse hair. The inner aspects are smooth but have numerous sebaceous follicles.

Labia minora

The labia minora are two small vascular folds of skin, containing sebaceous glands but devoid of adipose tissue, which lie within the labia majora. Anteriorly, they divide into two to form the prepuce and frenulum of the clitoris. Posteriorly, they fuse to form a fold of skin termed the 'fourchette'. They are not well developed before puberty, and atrophy after the

menopause. Their vascularity allows them to become turgid during sexual excitement.

Clitoris

This is a small erectile structure, approximately 2.5 cm long, homologous with the penis but not containing the urethra. The body of the clitoris contains two crura, the corpora cavernosa, which are attached to the inferior border of the pubic rami. The clitoris is covered by ischiocavernosus muscle, whilst bulbospongiosus muscle inserts into its root. The clitoris has a highly developed cutaneous nerve supply and is the most sensitive organ during sexual arousal.

Vestibule

The vestibule is the cleft between the labia minora. The vagina, urethra, paraurethral (Skene's) duct and ducts of the greater vestibular (Bartholin's) glands open into the vestibule (see Figure 1.7). The vestibular bulbs are two masses of erectile tissue on either side of the vaginal opening, and contain a rich plexus of veins within bulbospongiosus muscle. Bartholin's glands, each about the size of a small pea, lie at the base of each bulb and open via a 2 cm duct into the vestibule between the hymen and the labia minora. These glands secrete mucus, producing copious amounts during intercourse to act as a lubricant. They are compressed by contraction of the bulbospongiosus muscle.

Perineal body

This is a fibromuscular mass occupying the area between the vagina and the anal canal. It supports the lower part of the vagina and is of variable length. It is frequently torn during childbirth.

Age-related changes

In infancy, the vulva is devoid of hair and there is considerable adipose tissue in the labia majora and the mons pubis

Figure 1.6 Female external genitalia with the labia majora and minora separated.

Figure 1.7 Dissection of the female perineum to show the bulb of the vestibule and the greater vestibular gland on the right; on the left side of the body, the muscles superficial to these structures have been left *in situ*.

which is lost during childhood but reappears during puberty, at which time hair grows. The vaginal opening tends to widen and sometimes shorten after childbirth. After the menopause, the skin atrophies and becomes thinner and drier. The labia minora shrink, subcutaneous fat is lost and the vaginal orifice becomes smaller.

The Ureter

The ureters are a pair of muscular tubes which convey urine to the bladder by peristaltic action. They are between 25 and 30 cm in length, and approximately half of their course lies within the abdomen and half within the pelvis. Each has a diameter of approximately 3 mm but there are slight constrictions as they cross the brim of the lesser pelvis and when they enter the bladder.

Structure

The ureter has three layers. The outer fibrous coat merges inferiorly with the bladder wall. The middle muscular layer has outer circular and inner longitudinal non-striated fibres, plus a further outer longitudinal layer along the lower third of the ureter. The inner mucous coat is lined with transitional epithelium and is continuous with the mucous membrane of the bladder below.

Relations and course

Throughout its abdominal course, the ureter travels retroperitoneally along the anteromedial aspect of the psoas major and is crossed by the ovarian vessels. The right ureter passes down just laterally to the inferior vena cava, and must be carefully retracted away if dissection of the nodes of the inferior vena cava is necessary.

The ureter enters the pelvis anterior to the sacroiliac joints and crosses the bifurcation of the common iliac artery. It then passes along the posterolateral aspect of the pelvis, running in front of and below the internal iliac artery and its anterior division, medial to the obturator vessels and nerves.

On reaching the true pelvis, the ureter turns forwards and medially, passing lateral to the uterosacral ligaments. It then travels through the base of the broad ligament and, lateral to the cervix, is crossed superiorly from the lateral to the medial side by the uterine artery. It continues, running approximately 1.5 cm lateral to the cervix, anterolateral to the upper part of the vagina and, passing slightly medially, enters the bladder at the trigone.

Surgical injury

The ureter can be damaged during gynaecological surgery at a number of points in its course. It can be injured near the pelvic brim where it is adjacent to the ovarian vessels or lower, near the cervix, where it crosses beneath the uterine vessels. The dangers are greater when the pelvis is distorted by fibroids or ovarian cysts, or the ureter's course is displaced by a broad ligament cyst. Damage can occur through the ureter being cut, crushed or ligated, and occasionally it may be devitalized by extensive dissection, especially at

Wertheim's hysterectomy. Occasionally, it is injured by high sutures near the cervix in a pelvic floor repair.

The Bladder

The bladder is a muscular reservoir capable of altering its size and shape depending on the amount of fluid it holds. It is a retroperitoneal viscus and lies behind the symphysis pubis. When empty, it is the shape of a tetrahedron, with a triangular base or fundus and a superior and two inferolateral surfaces. The two inferolateral surfaces meet to form the rounded border which joins the superior surface at the apex. The base and the inferolateral surface meet at the urethral orifice to form the bladder neck. As the bladder fills, it expands upwards and outwards and becomes more rounded. Normal bladder capacity is between 300 and 600 ml, but it can, in cases of urinary retention, contain several litres and extend as far as the umbilicus.

Vesical interior

The mucous membrane of the bladder is only loosely attached to the underlying muscular coat, so that it becomes irregularly folded when the bladder is empty. A triangular area, the trigone, is immediately above and behind the urethral opening; the posterolateral angles are formed by the ureteric orifices (Figure 1.8). The mucous membrane here is redder in colour, smooth and attached firmly to the underlying muscle. The superior boundary is slightly curved, the interureteric ridge.

The ureteric orifices are slit-like and approximately 2.5 cm apart in the contracted bladder. They enter the bladder at an oblique angle which helps to prevent reflux of urine during filling.

Structure

The wall of the bladder is in three layers. The outer serous coat, the peritoneal covering, is only present over the fundus. The muscular layer, the detrusor muscle, consists of three

Figure 1.8 Except where it is fixed at its base, the bladder is a highly distensible structure. Urinary continence probably depends on the physical relations of the fixed/mobile junction.

layers of non-striated muscle, inner and outer longitudinal layers and a middle circular layer.

The mucous membrane is entirely covered by transitional epithelium which is responsive to ovarian hormonal stimulation. There are no true glands in this layer.

Relations

Superiorly, the bladder is covered by peritoneum. This extends forwards on to the anterior abdominal wall and sideways on to the pelvic side walls where there is a peritoneal depression, the paravesical fossa. As the bladder fills, the peritoneum is displaced upwards anteriorly, so that suprapubic catheterization of the full bladder can take place without the peritoneal cavity being entered. Anteriorly, below the peritoneal reflection is the loose cellular tissue of the cave of Retzius.

Posteriorly, the base of the bladder is separated from the upper vagina by the pubocervical fascia. Above this is the supravaginal portion of the cervix. The peritoneal reflection is at the isthmus of the uterus to form a slight recess, the uterovesical pouch, which often contains coils of intestine.

Surgical injury

The bladder may occasionally be opened during abdominal hysterectomy. The trigone, being in close relation with the upper vagina and the anterior fornix, is rarely damaged and perforation is usually 3–4 cm above it and can be easily repaired without damage to the ureter. If the injury is not noted, however, a vesicovaginal fistula may result. Damage may also occur during anterior colporrhaphy or vaginal hysterectomy, especially if a previous repair has been performed.

The Urethra

The urethra begins at the internal meatus of the bladder and runs anteroinferiorly behind the symphysis pubis, immediately related to the anterior vaginal wall. It is approximately 4 cm long and 6 mm in diameter. It crosses the perineal membrane and ends at the external urethral orifice in the vestibule, approximately 2.5 cm behind the clitoris. Skene's tubules, draining the paraurethral glands, open into the lower urethra. These glands are homologous to the male prostate.

There are no true anatomical sphincters to the urethra. The decussation of vesical muscle fibres at the urethrovesical junction acts as a form of internal sphincter, and continence is normally maintained at this level. Urethral resistance is mainly due to the tone and elasticity of the involuntary muscles of the urethral wall and this keeps it closed except during micturition. Approximately 1 cm from its lower end, before it crosses the perineal membrane, the urethra is encircled by voluntary muscle fibres, arising from the inferior pubic ramus, to form the so-called 'external sphincter'. This sphincter allows the voluntary arrest of urine flow.

Structure

The urethra has mucous and muscular coats. Near the bladder, the mucous membrane is lined by transitional epi-

thelium which gradually converts into non-keratinizing stratified squamous epithelium as it approaches the external urethral meatus. The muscular layer, consisting of inner longitudinal and outer circular fibres, is continuous with that of the bladder.

Relations

Anteriorly, the urethra is separated from the symphysis pubis by loose cellular tissue. Posteriorly is the anterior vaginal wall plus Skene's tubules. Laterally is the urogenital diaphragm, bulbospongiosus muscle and the vestibular bulb.

The Sigmoid Colon

The pelvic or sigmoid colon is continuous with the descending colon and commences at the brim of the pelvis. It forms a loop approximately 40 cm in length and lies in the lesser pelvis behind the broad ligament. It is entirely covered by peritoneum, which forms a mesentery, the sigmoid mesocolon, which diminishes in length at either end and is largest at mid-segment. The lower end of the colon is continuous with the rectum at the level of the third sacral vertebra.

Structure

The mucous membrane of the colon is thrown into irregular folds and is covered by non-ciliated columnar epithelium. Separated from this layer by areolar tissue is the muscle layer. This is arranged as an inner circular layer and an outer longitudinal layer which has three narrow bands, the taeniae coli. These bands are shorter than the general surface of the colon and therefore give it its typical sacculated appearance. A series of small pieces of fat, the appendices epiploicae, are attached to the serous coat.

Relations

The position and shape of the pelvic colon vary considerably and hence so do its relations. Inferiorly, it rests on the uterus and the bladder. Above and on the right are the coils of ileum; below and on the left is the rectum. Posterior relations also include the ureter, internal iliac vessels, piriformis muscle and sacral plexus, all on the left side. Lateral relations include the ovary, external iliac vessels and obturator nerve.

The Rectum

The rectum, which begins at the level of the third sacral vertebra, moulds to the concavity of the sacrum and the coccyx; its anteroposterior curve forms the sacral flexure of the rectum. It is approximately 12 cm in length. The lower end dilates to form the ampulla which bulges into the posterior vaginal wall and then continues as the anal canal. When distended, the rectum has three lateral curves; the upper and lower are usually convex to the right, and the middle is convex to the left. Peritoneum covers the front and sides of the upper third of the rectum and the front of the middle third. The lower third is devoid of peritoneum.

Structure

Unlike the sigmoid colon, there are no sacculations, appendices epiploicae or mesentery. The taeniae coli blend approximately 5 cm above the junction of the rectum and colon, and form two bands, anterior and posterior, which descend the rectal wall. When the rectum is empty, the mucous membrane is thrown into longitudinal folds which disappear with distension. Permanent horizontal folds are also present and are more pronounced during distension. The lining is of mucus-secreting columnar epithelium.

Anal canal

The anal canal is approximately 3 cm long and passes downwards and backwards from the rectum. It is slit-like when empty but distends greatly during defaecation. This is aided by the presence of fat laterally in the ischioanal fossa. Anteriorly, the anal canal is related to the perineal body and the lower vagina; posteriorly, it is related to the anococcygeal body.

For most of its length, it is surrounded by sphincteric muscles which are involved in the control of defaecation. The action of the levator ani muscles which surround it is also important in the control mechanism. The internal sphincter is involuntary and is a thickening of the circular muscle of the gut wall enclosing the anal canal just above the anorectal junction. The external sphincter is voluntary and composed of three layers of striated muscle.

Relations

The relations of the rectum are particularly important because they can be felt on digital examination. Posteriorly are the lower three sacral vertebrae, the coccyx, median sacral and superior rectal vessels. Posterolateral relations are the piriformis, coccygeus and levator ani muscles, plus the third, fourth and fifth sacral and coccygeal nerves. Below and lateral to the levator ani muscle is the ischioanal fossa (Figure 1.9).

Figure 1.9 The rectum has a rich anastomotic blood supply from the median sacral, the internal iliac and the inferior mesenteric arteries; this arrangement is reflected in its venous drainage.

Anteriorly, above the peritoneal reflection lie the uterus and adnexa, upper vagina and pouch of Douglas with its contents. Below the reflection, it is related to the lower vagina.

Pelvic Musculofascial Support

Pelvic peritoneum

Posteriorly, the peritoneum is reflected from the rectum on to the posterior wall of the vagina, at which point it is in close contact with the outside world; a fact that can be used both diagnostically and therapeutically. It then passes upwards over the cervix and the uterus to form the rectouterine pouch, the pouch of Douglas.

The peritoneum then passes over the fundus of the uterus and down its anterior wall to reach the junction of the body and cervix, where it reflects over the anterior wall of the bladder, forming a shallow recess, the uterovesical pouch. The peritoneum in front of the bladder is loosely applied to the anterior abdominal wall so that it strips away as the bladder fills. Suprapubic catheterization of the distended bladder can therefore be performed without entering the peritoneal cavity.

On either side of the uterus, a double fold of peritoneum passes to the lateral pelvic side walls, the broad ligament. These two layers, antero-inferior and postero-superior, enclose loose connective tissue, the parametrium. At the upper border, between the two layers, is the fallopian tube. The mesentery between the broad ligament and the fallopian tube is called the mesosalpinx, and that between the broad ligament and the ovary, the mesovarium (see Figure 1.3). Beyond the fallopian tube, the upper edge of the broad ligament, as it passes to the pelvic side wall, forms the infundibulopelvic ligament, or suspensory ligament of the ovary, and contains the ovarian blood vessels and nerves. Between the fallopian tube and the ovary, the mesosalpinx contains the vestigial epoophoron and paroophoron. After crossing the ureter, the uterine vessels pass between the layers of the broad ligament at its inferior border. They then ascend the ligament medially and anastomose with the ovarian vessels.

Pelvic ligaments

The round ligaments, a mixture of smooth muscle and fibrous tissue, are two narrow flat bands which arise from the lateral angles of the uterus and then pass laterally, deep to the anterior layer of the broad ligament, towards the lateral pelvic side wall. They then turn forwards towards the deep inguinal ring, crossing medial to the vesical vessels, obturator vessels and nerve, obliterated umbilical artery and external iliac vessels. They finally pass through the inguinal canal to end in the subcutaneous tissue of the labia majora. Together with the uterosacral ligaments, the round ligaments help to keep the uterus in a position of anteversion and ante-flexion.

The ovarian ligaments, which are fibromuscular cords of similar structure to the round ligament, lie within the broad ligament and each runs from the cornu of the uterus to the medial border of the ovary. Together, the round and ovarian

Figure 1.10 Pelvic musculature. Muscles leave the pelvis either above the superior ramus of the pubis or through the greater or lesser sciatic foramina. Nerves and vessels also leave via the obturator foramen.

Figure 1.11 Muscles of the pelvic floor. The slings of muscle that surround and separate the major body effluents have an important role as sphincters. 1, rectum; 2, internal anal sphincter; 3, external anal sphincter.

ligaments form the homologue of the gubernaculum testis of the male.

In addition, there are also condensations of pelvic fascia on the upper surface of the levator ani muscles, the so-called 'fascial ligaments', composed of elastic tissue and smooth muscle. They are attached to the uterus at the level of the supravaginal cervix and, being extensive and strong, have an important supporting role. The transverse cervical or cardinal ligaments pass laterally to the pelvic side wall and their posterior reflection continues around the lateral margins of the rectum as the uterosacral ligaments. They insert into the periosteum of the fourth sacral vertebra. These ligaments provide the major support to the uterus above the pelvic dia-

phragm, helping to prevent uterine descent. The uterosacrals also help to pull the supravaginal cervix backwards in the pelvis to assist in antelexion. Anteriorly, the pubocervical fascia is more of a fascial plane than a distinct ligament. It extends beneath the base of the bladder, passing around the urethra and inserting into the body of the pubic symphysis. It supports the bladder base and the anterior vaginal wall.

Pelvic musculature (Figures 1.10 and 1.11)

The levator ani and coccygeus muscles on either side, together with their fascial coverings, form the pelvic diaphragm which separates the structures in the pelvis from the perineum and the ischiorectal fossa. This diaphragm, together with all the tissue between the pelvic cavity and the perineum, makes up the pelvic floor. In lower mammals, the diaphragm represents the abductor and flexor muscles of the tail; in humans, who have an erect attitude, these muscles help to provide support to the pelvic viscera.

The levator ani is a wide, thin, curved sheet of muscle which arises anteriorly from the pelvic surface of the body of the pubic bone, the ischial spine and the tendinous arch of the obturator fascia between the two. The muscle fibres converge across the midline. The levator ani can be divided into three parts: puborectalis, which is most medial, encircling the rectum and vagina, and acting as support and additional sphincter for both; pubococcygeus, the strongest part of the muscular component, which is slung from the pubis to the coccyx; and iliococcygeus, the most posterior, also attached to the coccyx.

The posterior part of the pelvic floor is made up of coccygeus muscle, a thin, flat, triangular muscle, lying on the same plane as the iliococcygeal portion of the levator ani. It arises from the ischial spine and inserts into the lower sacrum and the upper coccyx. Like the levator ani, it acts by supporting the pelvic viscera.

Most of the side wall of the lesser pelvis is covered by the fan-shaped obturator internus muscle which is attached to the obturator membrane and the neighbouring bone. The fibres run backwards and turn laterally at a right angle to

Figure 1.12 The urogenital diaphragm. The floor of the pelvis slopes steeply forwards and plays an important role in continence and childbirth.

emerge through the lesser sciatic foramen. The side wall is covered medially by the obturator fascia (Figure 1.12).

The ischiorectal fossa, the wedge-shaped space lateral to the anus, is bounded laterally by the obturator internus and superomedially by the external surface of the levator ani. The base is the perineal skin. The fossa extends forwards, almost to the pubis, and backwards almost to the sacrum, where it is widest and deepest. The posterior boundary is made up by the sacrotuberous ligament and the gluteus maximus muscle, and the anterior boundary by the upper surface of the deep fascia of the sphincter urethrae muscle. It crosses the midline in front of the anal canal.

The musculature of the urogenital region can be divided into two groups, the superficial and deep muscles. Superficially, there are three muscles: the bulbospongiosus, the sphincter vaginae, which surrounds the vaginal orifice, posteriorly being continuous with the perineal body and anteriorly attaching to the corpora cavernosa of the clitoris; the ischiocavernosus, covering the unattached surface of the crus of the clitoris; and the superficial transverse perineal muscle. The deep muscles are the deep transverse perineal muscle, starting from the inner surface of the ischial ramus and passing to the perineal body, and the sphincter urethrae, surrounding the membranous urethra. These layers, and their fascial component, constitute the urogenital diaphragm.

The perineal body or central perineal tendon is a fibromuscular mass lying between the anal canal and the vagina. Superficially, it contains insertions of transverse perineal muscles and fibres of the external anal sphincter and, on a deeper plane, the levator ani muscle. It supports the lower part of the vagina and is frequently torn during childbirth.

Blood Supply to the Pelvis

Abdominal aorta

The abdominal portion of the aorta commences as it passes between the crura of the diaphragm at the level of the body

of the 12th thoracic vertebra. It runs downwards to the left of the midline along the front of the vertebral column, and bifurcates at the level of the body of the fourth lumbar vertebra to form the right and left common iliac arteries. The inferior vena cava runs immediately on its right. In the lower part of its course, ovarian and inferior mesenteric branches arise from the front of the aorta, and median sacral and lumbar branches arise from the back of the aorta.

Inferior mesenteric artery

The inferior mesenteric artery arises 3–4 cm above the bifurcation of the aorta. It descends at first in front of the aorta, then to the left of it, to cross the left common iliac artery medial to the left ureter, and continues in the mesentery of the sigmoid colon into the lesser pelvis. During its course, it gives off a left colic branch which supplies the left half of the transverse colon and descending colon, and a sigmoid branch supplying the sigmoid colon. In the lesser pelvis, it continues as the superior rectal artery, supplying the upper rectum and anastomosing with the middle and inferior rectal branches. The inferior mesenteric artery can occasionally be traumatized during para-aortic lymph node dissection and will bleed freely. Transection, however, is not of serious consequence to the blood supply to the lower bowel due to considerable anastomotic connections.

Common iliac artery

After the aortic bifurcation, the two common iliac arteries run a distance of 4–5 cm before again bifurcating to form internal and external iliac branches on either side. The left artery runs partly lateral and partly in front of the corresponding iliac vein. On the right side, the slightly longer artery runs in front of the lowermost portion of the inferior vena cava and the terminations of the two common iliac veins, and then anterior to the right common iliac vein. The bifurcation of the common iliac artery is in front of the sacroiliac joint. The ureter lies in front of the bifurcation at this point.

External iliac artery and its branches

The external iliac arteries are larger than the internal iliac vessels and run obliquely and laterally down the medial border of the psoas major. At a point midway between the anterior superior iliac spine and the symphysis pubis, the artery enters the thigh behind the inguinal ligament and becomes the femoral artery. At this point, it is lateral to the femoral vein but medial to the nerve. The ovarian vessels cross in front of the artery just below the bifurcation, as does the round ligament. The external iliac vein is partly behind the upper part of the artery, but medial in its lower part.

The external iliac artery gives off two main branches. The inferior epigastric artery ascends obliquely along the medial margin of the deep inguinal ring, pierces the transversalis fascia and runs up between the rectus abdominis muscle and its posterior sheath, supplying the muscle and sending branches to the skin. It anastomoses with the superior epigastric artery above the level of the umbilicus. The deep circumflex artery runs posteroinferior to the inguinal

ligament to the anterior superior iliac spine, and then pierces and supplies the transversus abdominis and internal oblique muscles.

Once the external iliac artery has pierced the thigh and become the femoral artery, it almost immediately gives off an external pudendal branch which supplies much of the skin of the vulva, anastomosing with the labial branches of the internal pudendal artery.

Internal iliac artery and its branches

The internal iliac arteries are 4 cm long and descend to the upper margin of the greater sciatic foramen where they divide into anterior and posterior divisions (Figure 1.13). In the fetus, they are twice as large as the external iliac vessels and ascend the anterior wall to the umbilicus to form the umbilical artery. After birth, with the cessation of the placental circulation, only the pelvic portion remains patent; the remainder becomes a fibrous cord, the lateral umbilical ligament. The ureter runs anteriorly down the artery and the internal iliac vein runs behind.

The posterior division has three branches which mainly supply the musculature of the buttocks. The iliolumbar artery ascends deep to the psoas muscle and divides to supply the iliacus and the quadratus lumborum. The lateral sacral arteries descend in front of the sacral rami and supply the structures of the sacral canal. The superior gluteal artery is the direct continuation and leaves the lesser pelvis through the greater sciatic foramen to supply much of the gluteal musculature.

The anterior division has seven main branches. The superior vesical artery runs anteroinferiorly between the side of the bladder and the pelvic side wall to supply the upper part of the bladder. The obturator artery passes to the obturator canal and thence to the adductor compartment of the thigh. Inside the pelvis, it sends off iliac, vesical and pubic branches (Table 1.1).

The vaginal artery corresponds to the inferior vesical artery of the male. It descends inwards, low in the broad ligament to supply the upper vagina, base of the bladder and adjacent rectum. It anastomoses with branches of the uterine artery to form two median longitudinal vessels, the azygos arteries of the vagina, one descending in front and the other behind.

The uterine artery passes along the root of the broad ligament and crosses above and in front of the ureter approximately 2 cm from the cervix. It then runs tortuously along the lateral margin of the uterus between the layers of the broad ligament. It supplies the cervix and the body of the uterus and part of the bladder, and one branch anastomoses with the vaginal artery to produce the azygos arteries. It ends by anastomosing with the ovarian artery (Figure 1.14). The branches of the uterine artery pass circumferentially around the myometrium, giving off coiled radial branches which end as basal arteries supplying the endometrium.

The middle rectal artery is a small branch passing medially to the rectum to vascularize the muscular tissue of the lower rectum and anastomose with the superior and inferior rectal arteries.

Figure 1.13 The blood supply to the pelvic viscera is derived in the main from the internal iliac artery.

Table 1.1 Arterial supply of the pelvic organs

Organ	Artery	Origin
Ovary	Ovarian	Aorta
	Uterine	Internal iliac
Fallopian tube	Ovarian	Aorta
	Uterine	Internal iliac
Uterus	Uterine	Internal iliac
	Ovarian	Aorta
Vagina	Vaginal	Internal iliac
	Uterine	Internal iliac
	Internal pudendal	Internal iliac
	Middle rectal	Internal iliac
Vulva	Internal pudendal	Internal iliac
	External pudendal	Internal iliac
Ureter	Renal	Aorta
	Ovarian	Aorta
	Uterine	Internal iliac
	Superior vesical	Internal iliac
	Inferior vesical	Internal iliac
Bladder	Superior vesical	Internal iliac
	Inferior vesical	Internal iliac
Urethra	Inferior vesical	Internal iliac
	Internal pudendal	Internal iliac
Sigmoid colon	Left colic	Inferior mesenteric
Rectum	Superior rectal	Inferior mesenteric
	Middle rectal	Internal iliac
	Inferior rectal	Internal pudendal (internal iliac)

Figure 1.14 The uterus has an anastomotic supply from both the ovarian and uterine arteries, both vessels running in the broad ligament.

The internal pudendal artery, the smaller of the two terminal trunks of the internal iliac artery, descends anterior to the piriformis and, piercing the pelvic fascia, leaves the pelvis through the inferior part of the greater sciatic foramen, crosses the gluteal aspect of the ischial spine and enters the perineum through the lesser sciatic foramen (Figure 1.15). It then traverses the pudendal canal with the pudendal nerve, approximately 4 cm above the ischial tuberosity. It then proceeds forwards above the inferior fascia of the urogenital diaphragm and divides into a number of branches. The inferior rectal branch supplies the skin and musculature of the anus, and anastomoses with the superior and middle rectal arteries; the perineal artery supplies much of the perineum, and small branches supply the labia, vestibular bulbs and vagina. The artery terminates as the dorsal artery of the clitoris.

The inferior gluteal artery, the larger terminal trunk, descends behind the internal pudendal artery, traverses the lower part of the greater sciatic foramen and, with the superior gluteal artery, supplies much of the buttock and the back of the thigh.

Nerve Supply to the Pelvis

Autonomic nerves (see Figure 1.15)

The internal pelvic organs are supplied by both the sympathetic and the parasympathetic autonomic nervous systems and this represents their sole innervation. As they descend into the pelvis, branches from the lower part of the lumbar sympathetic trunk join the aortic plexus of

Figure 1.15 Pelvic nerves and blood supply of the pudenda. The major nerve is the pudendal, but it is supplemented by the posterior cutaneous nerve of the thigh, and the ilioinguinal and genitofemoral nerves.

sympathetic nerves and ganglia as it continues downwards over the bifurcation of the aorta to form the superior hypogastric plexus. This then divides to form the right and left inferior hypogastric or pelvic plexuses, which lie lateral to the rectum and further subdivide into two, anteriorly innervating the base of the bladder and urethra and posteriorly innervating the uterus, cervix, vagina, sigmoid colon and rectum.

The parasympathetic nerves enter the pelvis through the second, third and fourth sacral nerves. The preganglionic fibres are distributed through the pelvic plexus, and the parasympathetic ganglia are situated close to, or in the walls of, the viscera concerned. With the exception of the ovaries and fallopian tube, which are supplied directly by nerves from the preaortic plexus travelling along the ovarian vessels, all internal pelvic organs are supplied via the pelvic plexuses.

Somatic nerves

The lumbar plexus is formed by the anterior primary rami of the first three lumbar nerves, part of the fourth nerve and a contribution from the 12th thoracic (subcostal) nerve. It lies on the surface of the psoas major and gives off a number of major branches.

The iliohypogastric and ilioinguinal nerves both arise from the first lumbar nerve. The former gives branches to the buttock, while the latter supplies the skin of the mons pubis and the surrounding vulva. The genitofemoral nerve arises from the first and second lumbar nerves, its femoral branch supplying the upper thigh, whilst its genital branch supplies the skin of the labium majus. The lateral femoral cutaneous

nerve arises from the second and third lumbar nerves, and also supplies the thigh.

The femoral nerve is the largest branch, coming from the second, third and fourth lumbar nerves. It descends in the groove between the psoas and iliacus muscles and enters the thigh deep to the inguinal ligament, lateral to the femoral artery, to supply the flexors of the hip, the extensors of the knee and numerous cutaneous branches including the saphenous nerve. The obturator nerve also comes from the second, third and fourth lumbar nerves, and passes downwards, medial to the psoas into the pelvis, to supply the adductor muscles of the hip.

The lumbosacral trunk comes from the fourth and fifth lumbar nerves, and passes medial to the psoas into the pelvis to join the anterior primary rami of the first three sacral nerves to form the sacral plexus in front of the piriformis muscle. From this plexus, a number of branches emerge. The most important of these are the sciatic nerve — a large nerve formed from the fourth and fifth lumbar nerves and the first, second and third sacral nerves — which leaves the pelvis through the lower part of the greater sciatic foramen to supply the muscles of the back of the thigh and the lower limb, and the pudendal nerve, formed from the second, third and fourth sacral nerves.

The pudendal nerve leaves the pelvis between the piriformis and coccygeus muscles and curls around the ischial spine to re-enter the pelvis through the lesser sciatic foramen where, medial to the internal pudendal artery, it lies in the pudendal canal on the lateral wall of the ischiorectal fossa. The point where the nerve circles the ischial spine is the region in which a pudendal block of local anaesthetic is injected.

The pudendal nerve gives a number of terminal branches. The inferior rectal nerve gives motor and sensory fibres to the external anal sphincter, anal canal and skin around the anus. The perineal nerve passes forwards below the internal pudendal artery to give labial branches, supplying the skin of the labia majora, the deep perineal nerve supplying the perineal muscles and the bulb of the vestibule. The dorsal vein of the clitoris passes through the pudendal canal, giving a branch to the crus and piercing the perineal membrane 1–2 cm from the symphysis pubis. It supplies the clitoris and surrounding skin.

Lymphatic Drainage of the Pelvis

In the pelvis, as elsewhere in the body, the lymph nodes are arranged along the blood vessels. The lateral aortic lymph nodes lie on either side of the aorta; their efferents form a lumbar trunk on either side which terminates at the cisterna chyli. Those structures which receive their blood supply directly from branches of the aorta, i.e. the ovary, fallopian tube, upper ureter and, in view of arterial anastomoses, uterine fundus, drain directly into the lateral aortic group of nodes.

The lymph drainage of most other structures within the pelvis is via more outlying groups of lymph nodes associated with the iliac vessels. The common iliac lymph nodes are grouped around the common iliac artery and are usually arranged in medial, lateral and intermediate chains. They receive efferents from the external and internal iliac nodes, and send efferents to the lateral aortics (Figure 1.16).

Figure 1.16 The lymph vessels and nodes of the pelvis.

Table 1.2 Lymphatic drainage of the pelvis

Organ	Lymph nodes
Ovary	Lateral aortic nodes
Fallopian tube	Lateral aortic nodes Superficial inguinal nodes External and internal iliac nodes
Corpus uteri	External and internal iliac nodes Superficial inguinal nodes Lateral aortic nodes
Cervix	External and internal iliac nodes Obturator node Sacral node
Upper vagina	External and internal iliac nodes Obturator node Sacral nodes
Lower vagina	Superficial inguinal nodes
Vulva	Superficial inguinal nodes Internal iliac nodes (deep tissues)
Ureter	Lateral aortic nodes Internal iliac nodes
Bladder	External and internal iliac nodes
Urethra	Internal iliac nodes
Sigmoid colon	Preaortic nodes
Upper rectum	Preaortic nodes
Lower rectum and canal	Internal iliac nodes
Anal orifice	Superficial inguinal nodes

The external iliac nodes lie on the external iliac vessels and are in three groups: lateral, medial and anterior. They collect from the cervix, upper vagina, bladder, deeper lower abdominal wall and inguinal lymph nodes. Inferior epigastric and circumflex iliac nodes are associated with these vessels and can be considered to be outlying members of the external iliac group (Table 1.2).

The internal iliac nodes, which surround the internal iliac artery, receive afferents from all the pelvic viscera, deeper perineum, and muscles of the thigh and buttock. The obturator lymph node, sometimes present in the obturator canal, and the sacral lymph nodes on the median and lateral sacral vessels can be considered to be outlying members of this group (Figure 1.17).

The upper group of superficial inguinal lymph nodes forms a chain immediately below the inguinal ligament. The lateral members receive afferents from the gluteal region and adjoining lower anterior abdominal wall. The medial members drain the vulva and perineum, lower vagina, lower anal canal, adjoining anterior abdominal wall and uterus owing to lymph vessels that accompany the round ligament to the anterior abdominal wall. The lymphatics on either side of the vulva communicate freely, emphasizing the importance of removing the whole vulva in cases of malignant disease. The superficial lymph nodes send their efferents to the external iliac lymph nodes, passing around the femoral vessels or traversing the femoral canal.

Figure 1.17 The lymphatic drainage of the female reproductive organs. Semi-diagrammatic after Cunéo and Marcille 1901, *Bull. Soc. Anat. Paris* 3,653.

Figure 1.18 Overview of the pelvis as seen from the umbilicus at laparoscopy.

The deep inguinal (femoral) lymph nodes, varying from one to three, are on the medial side of the femoral vein. They receive efferents from the deep femoral vessels and some from the superficial inguinal nodes; one, the node of Cloquet, is thought to drain the clitoris. Efferents from the deep nodes pass through the femoral canal to the external iliac group (Figure 1.18).

KEY POINTS

1. Knowing the course of pelvic migration of the ovaries is important in understanding the consequences of maldescent.
2. The sizes of the uterus and the cervix, and their ratio, change with age and parity.
3. The uterine artery is a branch of the internal iliac artery that crosses above the ureter and passes medially in the base of the broad ligament to reach the supravaginal portion of the cervix. It divides to pass superiorly alongside the body of the uterus, and inferiorly to supply the vagina and cervix.
4. The ovarian artery arises from the aorta at the level of the second lumbar vertebra. The right ovarian vein drains into the inferior vena cava, while the left ovarian vein drains into the left renal vein.
5. The inferior epigastric artery is a branch of the external iliac artery and ascends between the rectus muscle and the posterior rectus sheath, where it should be avoided during insertion of laparoscopic ports.
6. The ureter crosses the pelvic brim at the bifurcation of the common iliac artery and descends on the lateral pelvic side wall, where it is at risk during oophorectomy.
7. The ureter runs beneath the uterine vessels in the base of the broad ligament and emerges close to the supravaginal portion of the cervix (1.0–1.5 cm), where it is at risk during the ligation of pedicles at hysterectomy.
8. The internal urethral sphincter comprises two loops of smooth muscle fibres that pass around the vesical neck.
9. The term 'external urethral sphincter' refers to paraurethral striated muscle that is under voluntary control and includes the external, circular layer of urethral muscle together with the compressor urethrae and the urethrovaginal sphincter.
10. The pudendal nerve leaves the pelvis between the piriformis and coccygeus muscles, passes around the ischial spine and re-enters the pelvis via the lesser sciatic foramen, where it lies medial to the internal pudendal artery in the lateral wall of the ischiorectal fossa.

Introduction

Over the last century, uterine surgery has evolved from being dominated by hysterectomy to a range of less invasive procedures that have the common principle of conserving the uterus and reducing procedural morbidity. Disorders of the uterine cavity leading to abnormal uterine bleeding, infertility and pain affect the majority of women during their lifetime. The ability to view the uterine cavity has enabled the accurate diagnosis and treatment of numerous conditions. The quest to improve diagnostic and therapeutic capabilities has led to the widespread acceptance of modern gynaecological endoscopy.

Historical Development

Bozzini was the first to look into the cavity of a hollow organ, the bladder, in 1805. This was achieved with long tubes assisted by external illumination. In 1853, Desormeaux made the first satisfactory endoscope, but it was Panteleoni who performed the first satisfactory hysteroscopy in 1869 (Panteleoni 1869). Inability to distend the uterus and lack of proper illumination caused poor visualization and lack of widespread acceptance until Lindemann renewed Rubin's attempts to use carbon dioxide in the 1970s (Lindemann 1972).

Over the last three decades, improved optics and video monitoring systems have encouraged gynaecologists to learn this skill. Increased use and better understanding of electro-surgery have enabled significant developments in operative hysteroscopy. Smaller-diameter hysteroscopes have enabled hysteroscopy without anaesthesia, and outpatient hysteros-

copy is now firmly established. 'See and treat' in an outpatient hysteroscopy clinic is a reality in modern gynaecological practice.

Diagnostic Indications

Abnormal uterine bleeding

Menstrual abnormality is one of the most common reasons for referral to the gynaecological outpatient department. Menometrorrhagia, dysmenorrhoea and intermenstrual bleeding are the most common. After the menarche, such problems are usually dysfunctional, and hysteroscopy is rarely indicated. In postmenopausal patients, bleeding is a worrying symptom and warrants urgent attention as the patient is anxious to exclude endometrial cancer. Outpatient hysteroscopy offers rapid diagnosis and reassurance. In women of reproductive age, abnormal uterine bleeding can be associated with hormonal disturbances or pathology such as fibroids and polyps. Cervical polyps may be associated with endometrial polyps in 26.7% of patients (Stamatellos et al 2007), and exclusion of endometrial pathology is important.

Infertility

Hysteroscopy is a reliable method to detect and potentially treat submucous fibroids, endometrial polyps, intrauterine adhesions and endometritis. Congenital anomalies are infrequent but are associated with infertility. Abnormalities of the endometrium and organic intrauterine pathologies are important causes of failed in-vitro fertilization/embryo transfer cycles. A recent meta-analysis has shown potential

benefits of performing pretreatment hysteroscopy in patients being referred for IVF (El-Toukhy et al 2008).

Intrauterine synechiae (Asherman's syndrome)

Intrauterine adhesions can lead to infertility, recurrent miscarriage, hypomenorrhoea or amenorrhoea. Adhesions are caused by trauma to the endometrial basal layer, during evacuation of retained products of conception or may be secondary to infections (e.g. tuberculosis).

Fibroids and polyps

Submucous fibroids and polyps, which occlude the cervix or the tubal ostia, may hamper sperm progression and interfere with implantation.

Müllerian anomalies

Patients with a uterine structural anomaly may have normal fertility or present with infertility. Hysteroscopy may reveal arcuate, subseptate, septate, bicornuate or uterus didelphis. Hysterosalpingography, ultrasonography and laparoscopy are additional valuable tools to investigate these patients once an anomaly has been found.

Recurrent miscarriage

The aetiology of recurrent miscarriage is poorly understood. Intrauterine pathology such as fibroids, polyps, Asherman's syndrome or congenital abnormalities may be detected in up to 33% of infertile couples (Romano et al 1994). Implantation of an embryo over the septum or fibroid can also fail due to the poor blood supply in these parts of the uterus.

Foreign body

Missing threads of an intrauterine contraceptive device (IUCD) or a deeply embedded coil may need to be removed under hysteroscopic guidance. Apart from anxiety, these patients may present with menstrual irregularities and pain.

Chronic pelvic pain

Patients with chronic pain can pose a difficult challenge to the gynaecologist. Obstructive uterine anomaly may be associated in 40% of these patients (Schiffrin et al 1973). Concomitant hysteroscopy may reveal polyps, fibroids, adhesions and septate uterus which may contribute to the patient's symptoms.

Contraindications

Infection

Hysteroscopy in the presence of acute pelvic infection can lead to spread of infection with the distension medium flowing through the tubes, spreading the infection to the peritoneal cavity. The only exception is when infection is secondary to a lost IUCD, which should be removed hysteroscopically under antibiotic cover.

Pregnancy

Pregnancy is another contraindication, although embryoscopy prior to 10 weeks of gestation has been performed as an aid to prenatal diagnosis. Pregnancy leads to increased uterine softening and vascularity, increasing the risks of bleeding, uterine perforation and miscarriage. Hysteroscopy during pregnancy may occasionally be performed to remove a coil where the tails are not visible.

Malignancy

Hysteroscopy is contraindicated in the presence of cervical cancer. However, it is a gold standard procedure in patients with endometrial cancer as it aids directed biopsy.

Bleeding

Diagnostic hysteroscopy may be performed in the presence of bleeding, but the view is likely to be poor. Hysteroscopy is best performed in the mid-to-late proliferative phase when the endometrium is thinnest. If this is difficult to arrange, preoperative hormonal treatment with progesterone can help to postpone or control bleeding.

Cardiopulmonary disorders

Patients with these medical conditions are at higher risk of anaesthetic when recognized hysteroscopic complications, such as gas embolism and fluid overload, occur. Outpatient hysteroscopy under local anaesthetic is therefore the treatment of choice for such patients.

Cervical stenosis

Patients who have a history of cervical surgery or difficult uterine entry in the past are at increased risk of cervical trauma, perforation and false passage during the performance of a hysteroscopy. Prostaglandins inserted 2 h before hysteroscopy may help to soften the cervix, allowing easy dilatation and entry into the uterine cavity, although the evidence is limited for their value in postmenopausal patients (Crane and Healey 2006).

Instrumentation

Inadequate instrumentation resulting in poor visualization and reduced safety is not only dangerous, but will potentially give erroneous results. Good-quality hysteroscopes, cameras and driver units are basic requirements for good visualization of the uterine cavity. Appropriate fluid monitoring systems and energy sources, such as laser or diathermy, are essential for operative hysteroscopy (Figure 2.1).

Before commencing any hysteroscopic procedure, one must ensure that the stack system (Figure 2.2) is fully functional. This includes the telescope, surgical instruments, camera drive unit, camera head, light source, light lead, monitor, electrosurgical generator and image recording equipment. If a simultaneous laparoscopy is required, two stack systems should be made available. It is essential to assemble the equipment to ensure that it works prior to use. The distension medium, suction machine, fluid measurement apparatus and connecting tubing must be checked.

Fluid should be allowed to flow through the giving set to remove all air bubbles.

Optical systems

Rigid telescopes

Panoramic hysteroscopy is performed with the help of a distension medium, and is common practice. The majority of hysteroscopists use rigid telescopes. Improved technology has allowed significant reduction in the outer diameter (as low as 2.5 mm, including the inflow sheath). The outer diameter of operative hysteroscopes using monopolar electrosurgery may be up to 10 mm. This includes the telescope

Figure 2.1 Clinical anatomy of the uterus, showing the relation between the angle of the telescope, the light lead and the camera orientation.

with the working element, inflow sheath (inner) and outflow sheath (outer). Smaller-diameter operative scopes (Figure 2.3) measure 5 mm and consist of a 5 French operative channel communicating with the outflow sheath. This allows instruments of 5F diameter (e.g. the bipolar electrode, laser fibre, mechanical scissors and grasper) down the operative channel. The telescopes may be forward view (0°) or oblique view (angled scopes 12, 30, 70 or 90°).

Flexible telescopes

Flexible hysteroscopes offer the advantage of negotiating the scope along the uterine cavity with a 'no touch technique'. The tip can bend up to 110°, allowing easy uterine entry with minimal discomfort. Improved optics helps the image quality to be comparable with small rigid scopes. The risk of uterine perforation is reduced as the scope is able to

Figure 2.2 Stack system.

Figure 2.3 Bettochi hysteroscope.

negotiate the angle between the cervix and the uterus. The disadvantage is that continuous flow irrigation is not currently available for flexible hysteroscopy.

Hysteroscopic sheaths

For diagnostic panoramic hysteroscopy, a single sheath for inflow is sufficient. This enables a smaller outer diameter and outpatient hysteroscopy without anaesthesia. Operative hysteroscopy needs separate sheaths for inflow and outflow. The inflow sheath carries the distension medium to the tip of the telescope, from where it is withdrawn via the outer sheath (Figure 2.4). Fluid circulates over the tip of the telescope to maintain a clear view.

Camera and stack system

The hysteroscopic image is visualized on a monitor with the help of a camera connected to a camera drive unit. The image clarity of a single chip camera is perfectly adequate. Special weighted cameras are available and facilitate orientation, but the same camera as is used for laparoscopy is equally appropriate. It is important to 'white balance' the camera system to ensure that the colours are displayed correctly (see Figure 2.2).

Light source

A minimum power of 150 W is essential to obtain a clear image. It is essential to have a spare bulb and to know how to change it, as it can fail in the middle of a procedure. After use and between cases, if the light source is not going to be used for a short while, the bulb intensity should be turned down. Switching the light source on and off frequently reduces the bulb life.

Light lead

The optic fibres running along the light lead need careful handling and should never be rolled or kinked as the fibres break. Damaged fibres do not transmit light from the source, and give rise to poor illumination. The light lead should be checked before starting any procedure.

Monitor

The wiring and controls of the camera drive unit are often complex. The hysteroscopist should be familiar with the setting up of the system and able to rectify simple faults. One should always check that the monitor is displaying the appropriate image before commencing the procedure.

Image recording equipment

Images taken before and after the procedure can help patients to understand their clinical condition, and allow comparison with images obtained at a later date. Recorded images can serve as evidence in defence if there is a claim of medical negligence against the surgeon. Recordings of various hysteroscopic procedures can become useful teaching aids for trainees.

Distension medium

The anterior and posterior uterine walls are in apposition. In order to obtain a view, the uterine cavity has to be dis-

Figure 2.4 Continuous flow concept.

tended with gas or fluid. Carbon dioxide can be effective for diagnosis, and is delivered via a pressure reduction system or hysteroflator which is designed to give a maximum flow rate of 100 ml/min and a maximum pressure of 200 mmHg (note: a laproflator must not be used). An alternative is to use a liquid distension medium (e.g. normal saline or Hartmann's solution) which is appropriate for diagnosis and some operative procedures. Monopolar electrosurgery requires a non-conductive distension medium such as 1.5% glycine. However, it should be remembered that once the solution becomes contaminated with blood, its function as an insulator is reduced. Fluid can be pressurized via a roller pump (with maximum flow rate of 500 ml/min and maximum pressure of 200 mmHg), gravity or a pressure infusion bag cuff system. For diagnosis, gravity or a 50-ml syringe connected to a giving set via a three-way tap provides very good control of the distension pressure. Dextran 70 (Hyskon) is no longer used due to anaphylactic reactions.

Technique of Diagnostic Hysteroscopy

Clinical anatomy of the uterus

The uterine cavity is flat in its anterior/posterior dimension as, when not distended, the anterior and posterior endometrial surfaces are apposed to each other. The cervical canal is essentially round, but once the cavity is entered, the lateral dimension widens until it is at its broadest at the fundus. The cavity extends laterally towards the tubal ostia (see Figure 2.1). The fundal dome may be flat, concave or convex on its interior surface. Indeed, a proportion of uteri have a pronounced fundal convexity, a so-called 'arcuate deformity'.

Endometrial preparation

A diagnostic hysteroscopic examination is best performed without medical preparation of the endometrium. The endometrium will be at its thinnest in the immediate post-menstrual phase, and at its most vascular in the premenstrual phase. Abnormal bleeding is a common indication for diagnostic hysteroscopy, and whilst it is often possible to time the examination such that bleeding is not occurring,

light bleeding need not preclude successful examination of the endometrial cavity. When prolonged heavy bleeding occurs, norethisterone 5 mg three times daily for 7–10 days may be given prior to the examination. It is rarely necessary to use a gonadotrophin-releasing hormone (GnRH) analogue prior to a diagnostic procedure, but one to three doses are employed prior to endometrial ablation, or to shrink a vascular fibroid prior to operative hysteroscopic resection.

Anaesthesia

In the majority of cases, the smallest modern diagnostic hysteroscopes require no anaesthetic whatsoever. A crucial factor is good communication between the gynaecologist and the patient, with thorough preoperative counselling and the support of a skilled nurse who is able to complement the operator in explaining things to the patient. The role of local anaesthetic gels is open to question. They are inexpensive and certainly lubricate and cause the external os to open. They probably have little anaesthetic effect other than as a psychological adjunct to the gynaecologist's reassurance.

Where facilities do not exist for outpatient hysteroscopy, the procedure is carried out in the operating theatre. Whilst a 5-mm rigid diagnostic hysteroscope can be passed through the cervix in the majority of women of reproductive age, this can prove extremely difficult in postmenopausal women and cervical dilatation is often needed. This requires a paracervical block, a regional anaesthetic or a general anaesthetic. The choice of anaesthetic method will, of course, be decided in conjunction with the anaesthetist and the patient. The choice will, in part, be determined by the patient's state of health and whether any additional procedures are planned. It must be remembered, however, that those patients who are at risk of endometrial cancer in the postmenopausal period are often more obese and suffer from cardiovascular and airways disease. These render them at high risk from the anaesthetic point of view. Such patients provided a major stimulus to the establishment of outpatient diagnostic and, in some cases, therapeutic hysteroscopy services.

Positioning

Hysteroscopy can be performed on a general operating table equipped with lithotomy poles or Lloyd Davies supports. Care must be taken to avoid excessive pressure from the leg supports on neurovascular structures, and if there is limitation of joint movement owing to hip or knee pathology, the final position of the patient will have to be modified.

In the outpatient setting, a colposcopy chair is desirable. This allows a comfortable modified lithotomy position with minimum loss of dignity. It is essential that the patient should be kept covered until the examination is due to start.

Procedure

Inpatient/general anaesthetic

A pelvic examination is performed in order to determine the size and direction of the uterus. The vulva and vagina are cleaned with antiseptic solution, and the anterior lip of the cervix is grasped with a vulsellum forceps. The majority of rigid hysteroscopes offer a fore/oblique view ranging from

12 to 90°. By convention, the direction of the view is away from the light post. The camera system is attached to the scope with the camera orientated correctly and the light post either up or down such that the angled view is in the vertical plane. It is easier to follow the cervical canal if the scope is orientated to view along the direction of the canal (i.e. forwards and downwards in a retroverted retroflexed uterus). Crucial to obtaining a thorough hysteroscopic examination is an understanding of how rotation of the hysteroscope allows the area of uterine wall under inspection to be changed. The authors suggest holding the camera in one hand and maintaining the position of the camera fixed in relation to the vertical plane. Rotation of the scope by manipulating the light post with the other hand allows the view to be manipulated appropriately.

Insertion of the hysteroscope through the cervical canal should be performed under direct vision and, in the first instance, without cervical dilatation or the passage of a sound. This allows examination of the cervical canal and inspection of undamaged endometrium. Once instruments have been passed into the uterine cavity, they cause damage to and stripping of the endometrium, which can then give appearances suggestive of polyp formation. The image of the cervical canal during passage of the scope is, of course, dependent on the viewing angle of the scope. A 0° scope requires the cervical canal to be kept in the middle of the field of view during insertion to maintain the direction of travel of the scope parallel to the direction of the cervical canal. When an angled viewing scope is used, the position of the cervical canal in the field of view has to be offset in order to maintain the direction of travel of the hysteroscope parallel with the direction of the cervical canal. This is why orientation of the light post relative to the orientation of the camera is a crucial step in the assembly of the equipment, but it is often overlooked.

Once the cervical canal is passed, a panoramic view of the uterine cavity is obtained. Uterine distension at a flow rate of 40–60 cc/min with pressure between 40 and 80 mmHg achieves good visualization. The scope is advanced towards the fundus and rotated to allow inspection of the tubal ostia. The scope can then be withdrawn and readvanced whilst rotating it to enable systematic inspection of each uterine wall in turn.

Potential problems include blood accumulating in the cavity and obscuring the view. This can occur during diagnosis when the seal between the hysteroscope and the cervix is very tight, preventing outflow of distension medium. The passage of a dilator 1 mm greater than the outer diameter of the hysteroscope allows flow and clearance of the contaminating blood. If a large polyp is present in the endometrial cavity, it is possible to inspect the cavity without realizing that the polyp is there because the polyp fills the cavity and the scope has been passed beyond the tip of the polyp before inspection begins (Figure 2.5). Suspicion should be aroused if the endometrial surfaces are different in colour, and careful inspection of the panoramic view of the cavity during insertion and removal of the scope will avoid missing a large polyp as the tip of it will be seen. A thorough examination of the uterine cavity should allow inspection of both tubal ostia. A record of this in the operation notes demonstrates that the operator has obtained a good view.

Figure 2.5 (A) Transvaginal sonography showing polyp. (B) Sonohysterography with polyp clearly outlined.

Postoperative care

The majority of the recovery process after a diagnostic hysteroscopy relates to recovery from the anaesthetic. A small amount of vaginal bleeding is not unusual following hysteroscopy, and the patient should be warned about this. Occasionally, cramping period-like pains are experienced; these should settle within 48 h and respond to paracetamol or a non-steroidal anti-inflammatory drug such as mefenamic acid. Persistent pain and bleeding may suggest a complication such as endometritis, and the patient should seek medical help. The provision of a postprocedure information leaflet is good practice.

Hysteroscopy in outpatients

Provision of hysteroscopy combined with transvaginal ultrasound in outpatients provides a very efficient method of assessing women with pre- and postmenopausal bleeding. As mentioned above, many patients who require a hysteroscopy pose significant risk for general anaesthesia, and are best managed under local or no anaesthetic (Valli et al 1998). In addition, there are many advantages to the patient, including shorter time at the hospital and more rapid return to normal activity. There are also cost advantages to the hospital, as an outpatient clinic is clearly a less expensive environment than an operating theatre (Marsh et al 2004).

Choice of equipment

Choice of equipment will vary with the prior experience of the operator and the facilities available for disinfection/sterilization of the instruments. Rod lens hysteroscopes may be autoclaved, necessitating the provision of an adequate number of scopes for a session of activity. Fibreoptic hysteroscopes, whether rigid or flexible, cannot be autoclaved and must be sterilized with ethylene oxide or closed liquid disinfection systems.

In reality, there are disadvantages and advantages of every system. Rigid autoclavable scopes tend to be of larger diam-

eter, necessitating cervical dilatation in a proportion of cases. The advantage is clarity of view and a fore/oblique view allowing easier examination of the cornua. Flexible scopes are delicate and more expensive, but allow steering through the cervical canal and angulation to allow full inspection of the uterine cavity without any anaesthesia (Kremer et al 1998) (Figure 2.6A). Fibreoptic rigid scopes can be of very small diameter (1.2 mm in a 2.5-mm diagnostic sheath) (Figure 2.6B). They are 0° so viewing of the cornua is more difficult, but they are relatively easy to pass through stenosed postmenopausal cervixes, leading to a very low failure rate. The Versascope system provides a disposable sheath which can be distended by the passage of a 5 French instrument. This means that a change of sheath is not required to convert a diagnostic procedure into an operative procedure.

Hysteroscopy technique

In the outpatient setting, the authors favour a Cusco's speculum to bring the cervix into view prior to introduction of the hysteroscope. This allows manipulation of the position of the cervix with the speculum as the scope is inserted to straighten the cervical canal. Rarely, it is necessary to grasp the cervix with a single-toothed tenaculum. Others use no speculum at all when performing vaginoscopy, and locate the cervix before inserting the hysteroscope into it. With the patient awake and the gynaecologist concentrating on passing the scope through a difficult cervix, the role of the attending nurse is paramount (Prather and Wolfe 1995). The nurse should have a good knowledge of the procedure, excellent communication skills and be able to maintain a rapport with the patient during the procedure. Preprocedure explanatory leaflets and a brief discussion help to reassure the patient, who often finds that the procedure causes less discomfort than is anticipated. Patients vary in their wish to see the television screen during the procedure, but the majority find it reassuring and helpful to be able to view the image of the uterine cavity. This also allows easier explanation of any pathology found.

Figure 2.6 (A) Flexible hysteroscope. (B) Rigid outpatient hysteroscope.

Endometrial sampling

Endometrial sampling that only yields a small percentage of the endometrium causes discomfort that is often greater than that of the hysteroscopy. It is not indicated in all cases, and in particular should be avoided in patients with post-menopausal bleeding in whom the endometrium is found to be atrophic on hysteroscopy. An 'inadequate for diagnosis — malignancy cannot be excluded' report on histology confounds the picture and leads to further unnecessary procedures. Hysteroscopically-directed biopsy often results in a sample which is so small that it is difficult for the pathologist to orientate.

Pathology Seen at Diagnostic Hysteroscopy

The diagnostic hysteroscopist should familiarize him-/herself with the normal appearances of the endometrium during the phases of the endometrial cycle and during the menopause (Figure 2.7). The endometrium should be assessed for colour, texture, vascularity and thickness. An impression of thickness can be gained by pressing the surface of the endometrium with the end of the hysteroscope. Post-menopausal atrophy is characterized by very thin pale endometrium, often accompanied by a ridged appearance.

Endometrial polyps (Figure 2.8A) can vary considerably in appearance, and the observer should define the position and size of the base of the polyp to aid subsequent operative hysteroscopy. Fibroids (Figure 2.8B) have a characteristic whitish appearance, and often have clearly visible surface vessels. Submucous fibroids which bulge significantly into the uterine cavity may remain covered with endometrium, but do not often have an appearance similar to that of a fibroid polyp. An assessment should be made of the relative proportion of the fibroid which is bulging into the endometrial cavity, as this determines whether it is likely to be resectable during a single operative procedure or may require multiple attempts.

A uterine septum (Figure 2.8C) may be seen dividing the cavity into two halves, while intrauterine adhesions (Figure 2.8D) can lead to complete disruption of the cavity. An IUCD (Figure 2.8E) is the most common foreign body seen at diagnostic hysteroscopy.

Figure 2.7 Premenstrual endometrium.

Hyperplastic endometrium is thickened, often polypoid and has increased vascularity (Figure 2.9). Endometrial cancer is often friable, sometimes has a lobed appearance and may appear necrotic. It should be suspected in post-menopausal patients where only a poor view is obtained due to excessive bleeding. Tamoxifen causes a specific pattern of hyperplasia associated with a vesicular appearance.

Hysteroscopic Skills

The Royal College of Obstetricians and Gynaecologists (RCOG) report on minimal access surgery categorized skill levels in training in both laparoscopy and hysteroscopy (Royal College of Obstetricians and Gynaecologists 1994). Hysteroscopic procedures were divided into three levels, with the first level covering diagnostic and simple procedures such as the removal of a foreign body (Box 2.1). The second level contains operative procedures, such as resection or ablation of the endometrium, and removal of polyps and fibroids. Advanced procedures (third level) include repeated

Figure 2.8 (A) Versapoint spring electrode at the base of a polyp. (B) Submucous fibroid polyp. (C) Intrauterine septum. (D) Intrauterine adhesion. (E) Intrauterine foreign body.

Figure 2.9 Endometrial hyperplasia.

Box 2.1 Stratification of hysteroscopic procedures by level of training

Level 1. Diagnostic procedures

- Diagnostic hysteroscopy plus target biopsy
- Removal of simple polyp
- Removal of IUCD

Level 2. Minor operative procedures

- Proximal fallopian tube cannulation
- Minor Asherman's syndrome
- Removal of pedunculated fibroid or large polyp

Level 3. More complex operative procedures requiring additional training

- Division/resection of uterine septum
- Endoscopic surgery for major Asherman's syndrome
- Endometrial resection or ablation
- Resection of submucous leiomyoma
- Repeat endometrial resection or ablation

Source: Royal College of Obstetricians and Gynaecologists (RCOG) 1994 Report of Working Party on training in gynaecological endoscopic surgery, RCOG Press, London.

resection or ablation, and treatment of extensive uterine synechiae. The RCOG established a subcommittee of the training committee to supervise training in minimal access surgery, and has since designed an advanced training module in benign gynaecological surgery which covers both diagnostic and operative hysteroscopy. It is mainly aimed at senior specialist registrars in obstetrics and gynaecology in their final 2 years of training. By completion of the module, ideally within 1 year, trainees are expected to have reached independent competence in performing both diagnostic and operative hysteroscopy. The trainee has to register with their preceptor and training programme director, who supervise and train the trainee in the practical aspects of outpatient diagnostic and operative hysteroscopy.

In addition, the trainee has to attend a practical training course in hysteroscopy. It is also recommended that trainees should attend the hands-on skills station in a training laboratory.

Training and learning curve

Hysteroscopy is a relatively simple surgical skill to learn, provided that the surgeon undergoes a structured training process. It is clear that familiarity with equipment and knowledge of the basic underlying principles should be imparted early in the training process. To this end, the basic skills course in obstetrics and gynaecology provides an introduction to these skills. Manipulating hysteroscopes and a camera system on models allows an early grasp of the basic principles of the orientation, and allows the trainee to progress rapidly to successful diagnostic hysteroscopy on anaesthetized patients. Outpatient diagnostic hysteroscopy requires considerable skill, confidence and familiarity with the equipment. It should be reserved for consultants and senior trainees with a specific interest.

It has been shown that achieving the operative hysteroscopy skills has a steep learning curve. A recent survey of trainees registered for the hysteroscopy module showed that the 1-year target for obtaining the special skills module was difficult to achieve, with the most evident cause being the inability to acquire the expected operative hysteroscopy standard within the intended time (Shoukrey et al 2008).

Therapeutic strategy for benign disease

Identification of focal intracavity lesions

- Fibroids.
- Polyps.
- Uterine anomalies.
- Foreign bodies.

Dysfunctional uterine bleeding

While focal intracavity lesions need operative hysteroscopic treatment, treatment of abnormal uterine bleeding has changed over the last few years. These conservative non-hysteroscopic treatments will be reviewed later in this chapter.

Indications for operative hysteroscopy

- Polyp or fibroid more than 2 cm in diameter.
- Uterine adhesions.
- Uterine anomalies.

Instrumentation for operative hysteroscopy

Operative hysteroscopy generally requires a larger instrument and a continuous flow sheath. In addition, a source of energy is used to perform the required manipulations.

Mechanical

Scissors and grasping forceps are passed down the operating channel of the hysteroscope, and can be used to cut the stalk of simple polyps, which are then grasped with forceps for removal (Figure 2.10). Lost foreign bodies such as IUCDs can be removed in a similar fashion.

Monopolar electrical

Monopolar electrosurgery requires flow of radiofrequency electric current from the active tip of the instrument through

Figure 2.10 Mechanical instruments for operative hysteroscopy.

the patient to the large surface area return plate. The electrical effect depends on both current density and the waveform provided by the generator. Simple instruments for use with monopolar diathermy include a polyp snare and simple electrodes, which can be passed down a 5 French operating channel. A dedicated continuous flow hysteroscope is required for more sophisticated operative instruments, including a resection loop, knife, rollerball and cylinder (Figure 2.11).

Trancervical resection of the endometrium (TCRE) is a popular technique for endometrial destruction in which the loop is used to cut away the prepared endometrium down to the myometrium. Figure 2.12A demonstrates the loop in use, and the transverse myometrial fibres can be seen clearly. Movement of the loop within the hysteroscope sheath and withdrawal of the scope itself allow long strips of endometrium to be resected. Removal of the tissue strips maintains a clear view. Most operators start with the posterior wall in order that the resected tissue strips do not obscure the working area. Considerable training is needed to ensure safe use of this technique. Difficult areas to treat include the cornua where the myometrium is thin, and the fundus where the resection loop has to be bent forwards in order to achieve a cutting effect in front of the tip of the hysteroscope. Cornual

Figure 2.11 (A) Working elements for operative hysteroscopy. (B) Assembled resectoscope. (C) Components of resectoscope.

Figure 2.12 (A) Endometrial resection. (B) Rollerball ablation. (C) Laser ablation.

endometrium may be ablated with a rollerball and combined with resection of the remaining endometrium (Figure 2.12B). A Scandinavian study (Furst 2007) reported long-term follow-up of TCRE. This showed 80% patient satisfaction, and 20% of patients required hysterectomy at the end of 10 years.

The same instrument is used for resection of submucous fibroids and fibroid polyps, whilst the knife is employed for the treatment of Asherman's syndrome and uterine septae. The resectoscope system is inexpensive as it uses reusable electrodes, which are autoclavable. A careful watch must be kept on the fluid balance during the procedure, as overload of 1.5% glycine solution may lead to significant complications. More than 1 l of solution lost into the patient poses significant risk, and the procedure should be abandoned if such levels of fluid loss are significantly exceeded. Laser destruction is an alternative (Figure 2.12C).

Bipolar electrosurgery

Versapoint (Figure 2.13A) is a 5 French electrode. It requires a dedicated electrosurgery generator, which pulses the electrical energy through the saline irrigation medium from the active electrode tip to the larger return sleeve (Figure 2.13B). This creates a vapour pocket around the active electrode, and when tissue enters the vapour pocket, the high current density causes vaporization of the tissue. This device has been used for vaporizing fibroids and polyps. It is suitable for use under local anaesthetic, particularly in conjunction with the Versascope. The Versapoint resection system, a larger version using similar technology, is suitable for the removal of larger fibroids under general anaesthetic (Figure 2.13C). Bipolar electrodes appear to have a safer profile compared with monopolar electrodes because of the unchanged serum sodium. Irrigant consumption has been reported to be significantly higher in the two bipolar groups, without any side-effects during or after the procedure. Furthermore, the TCRE loop appears to be superior to the Versapoint loop in terms of operating time and amount of tissue removed (Berg et al 2009).

Endometrial destruction

The in-vivo studies of Duffy et al (1992) demonstrate that rollerball coagulation results in thermal necrosis to a depth of 3.3–3.7 mm. The depth of cut with a resection loop is 3–4 mm. Endometrial thickness, however, varies from 3 to 12 mm during the menstrual cycle. Therefore, satisfactory ablation can only be achieved if surgery is performed in the immediate postmenstrual phase. This leads to a shorter duration of surgery, greater ease of surgery and a high rate of postoperative amenorrhoea (Sowter et al 2001).

A national survey of the complications of endometrial destruction for menstrual disorders, the MISTLETOE study (Overton et al 1997), compared the different surgical techniques for endometrial destruction. Combined diathermy resection appeared safer than resection alone, but laser and rollerball ablation were the safest. Fibroids were associated with associated increased operative haemorrhage. Increasing operative experience was associated with fewer uterine perforations in the loop resection alone group, but had no effect on operative haemorrhage in any group. Cumulative failure rate at 1 year for combined resection and rollerball ablation was lowest at 15%, compared with 20% for resection or rollerball ablation alone, and 32% for laser ablation.

Comparison of endometrial destruction methods with hysterectomy revealed that they have less postoperative morbidity, shorter hospital stay, and quicker return to work, normal activity and sexual intercourse compared with

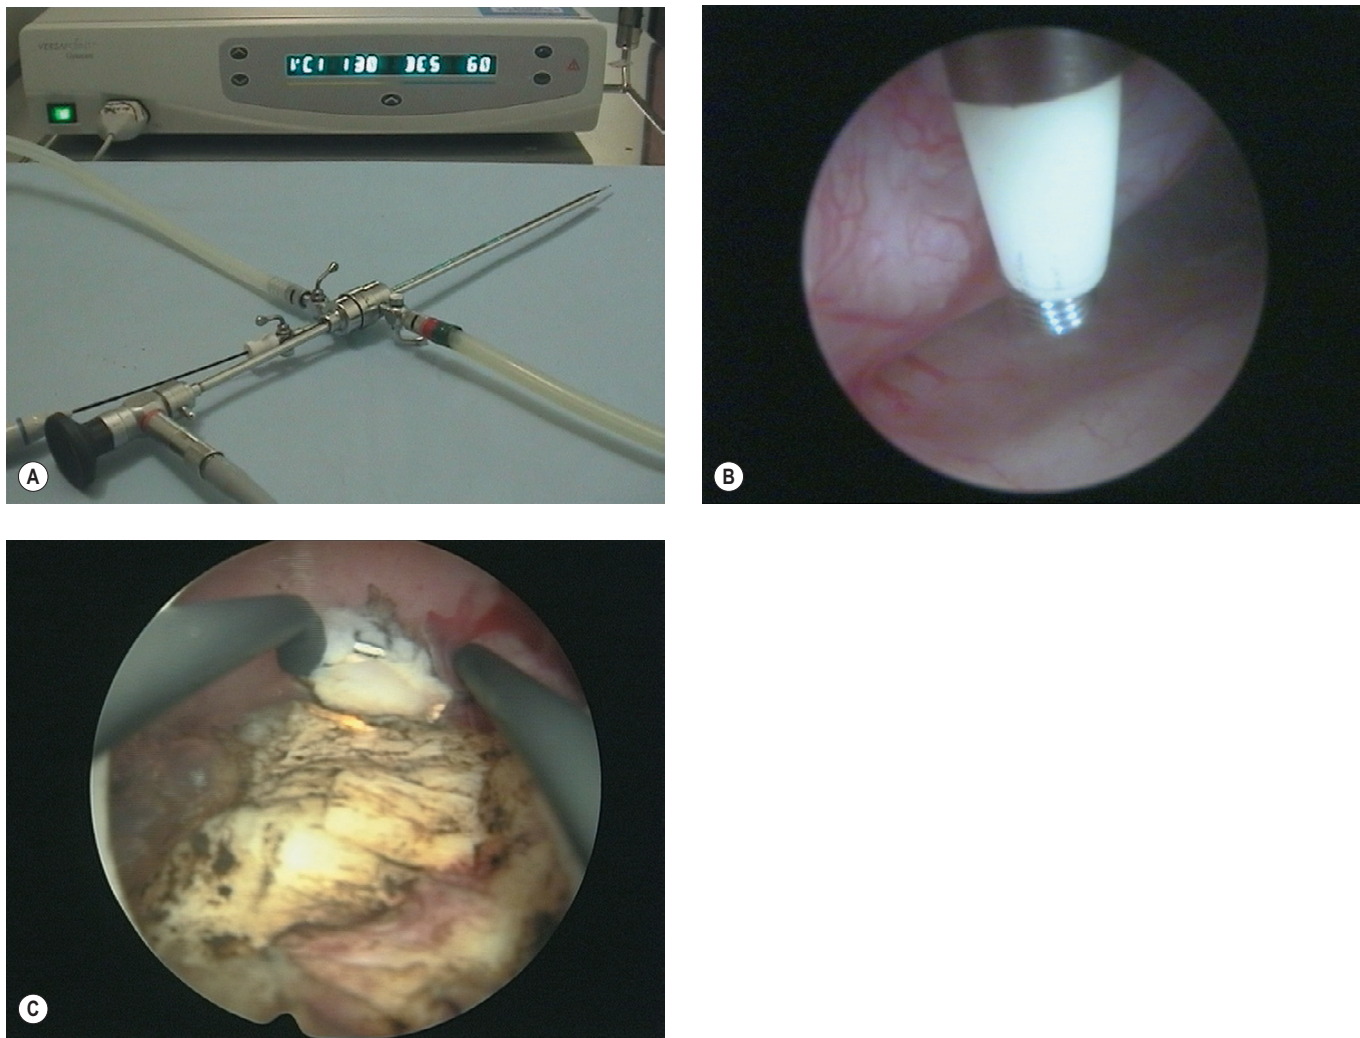

Figure 2.13 (A) Bettocchi with Versapoint. (B) Versapoint spring electrode at polyp base. (C) Versapoint resection system.

hysterectomy, but patient satisfaction may be slightly higher following hysterectomy (Pinion et al 1994).

As with all ablation techniques, success is dependent on the proximity of the menopause, with postoperative amenorrhoea rates being highest in the older age group. Adenomyosis is a major cause of failure.

Non-operative methods of endometrial ablation and the use of the levonorgestrel-releasing intrauterine device (LNG IUS) for the treatment of menorrhagia have decreased the use of endometrial resection to treat dysfunctional uterine bleeding. The LNG IUS results in a smaller mean reduction in menstrual blood loss than TCRE and women are not as likely to become amenorrhoeic, but there is no difference in the rate of satisfaction with treatment (Lethaby et al 2005). In fact, in the meta-analysis of six randomized clinical trials, the efficacy of the LNG IUS in the management of heavy menstrual bleeding appears to have similar therapeutic effects to endometrial ablation up to 2 years after treatment (Kaunitz et al 2009).

Polypectomy and myomectomy

Hysteroscopic polypectomy and myomectomy are dependent on the experience of the operator and the size and posi-

tion of the fibroid. Removal of the polyp can be as difficult as detaching it. If the polyp is small enough, grasping it with forceps, pulling it against the end of the scope and then withdrawing the whole scope can be effective. An alternative is to remove the detached polyp blindly using polyp forceps. This is often difficult and serves to illustrate the futility of blind techniques.

Fibroids under 2 cm in size can be resected in one sitting. For larger fibroids or those where more than half is intramural, a two-stage procedure may be necessary. In the first stage, the protruding portion of the fibroid is removed, followed by transhysteroscopic myolysis of the intramural portion (Donnez and Nisolle 1992). Subsequently, GnRH agonist therapy for 8 weeks shrinks the uterine cavity, extruding the intramural portion of the fibroid, which is then easily removed at the second stage to complete the myomectomy. Complete removal of the fibroid is associated with improved long-term results (Wamsteker et al 1993).

Uterine adhesions and septae

The division of dense uterine synechiae (Figure 2.14) and uterine septae requires considerable skill and is often

Figure 2.14 Division of intrauterine synechiae with scissors.

performed under laparoscopic guidance, which ensures that thermal or electrical energy is not allowed to penetrate through the myometrium, damaging the adjacent bowel. Careful assessment prior to division of uterine septae is essential to prevent perforation at the fundus. The hysteroscopic appearances of a septate uterus and a uterus didelphys can be similar, and any attempt to resect the septum will clearly lead to disaster in the latter case. Careful ultrasound evaluation helps to differentiate between the two, but this has not yet replaced laparoscopic assessment. After adhesiolysis, an IUCD may be inserted for 3 months to prevent reformation of the adhesions. Similarly, postoperative hormone therapy may be initiated to help endometrial development and prevent further adhesion formation (Gordon et al 1995).

Operative hysteroscopy in the outpatient unit will be feasible in future. Authors have carried out transcervical resection procedures under local anaesthetic in daycare settings and have found a high level of patient satisfaction. A recent study has shown that this procedure is feasible with the availability of a mini-resectoscope (Papalampros et al 2009).

Treatment of the Endometrial Cavity without Intracavity Lesions

Menorrhagia has always been a major health problem in premenopausal women. Its treatment has evolved from hysterectomy at one end of spectrum to less invasive procedures at the other. All the treatment modalities aim to destroy the basal endometrium, preventing its regeneration. First-generation techniques use operative hysteroscopy procedures. Second-generation devices have been developed to achieve the results of first-generation techniques using simpler procedures. The use of these techniques obviates the need of hysteroscopic expertise, general anaesthesia and dilatation of the cervix, and therefore can be applied more widely.

Second-generation techniques have shown comparable quality-of-life improvements and patient satisfaction rates with first-generation techniques, along with comparable success rates and complication profiles (Lethaby et al 2005).

Figure 2.15 Thermal balloon ablation system.

Thermal balloon ablation (Thermachoice, Gynaecare Ethicon Ltd, Somerville, NJ, USA)

Thermachoice is a silicone balloon catheter system which is inserted into the uterine cavity and inflated with 5% dextrose solution to achieve a pressure of 160–180 mmHg. The dextrose is heated to a temperature of 87° when the treatment cycle starts and continues for 8 min.

The procedure does not require any dilatation and is feasible to perform in an outpatient setting (Andersson and Mints 2007, Clark and Gupta 2004). The National Institute for Health and Clinical Excellence (NICE) has approved and validated the clinical safety and effectiveness of thermal ablation (see Figure 2.15).

A large multicentre observational study showed a significant reduction in the severity and duration of menstrual loss (Amso et al 1998). Thermachoice achieved a reduction in menstrual blood loss that was comparable with the first-generation techniques. In a long-term multicentre study, Thermachoice showed an 86% probability of avoiding a hysterectomy at 4–6-year follow-up (Amso et al 2003).

Other thermal balloons used in ablation are Cavaterm and Thermablate.

Cryoablation (Her Option, Uterine Cryoablation Therapy System, Cryo-gen Inc., San Diego, CA, USA)

The principle of cryotherapy is used for cryoablation. Liquid nitrogen is used to produce extreme cooling, producing an iceball at the tip of the cryoprobe. The probe is moved from one cornua to the other and through the entire cavity in a series of freeze–thaw cycles. Ultrasound guidance is needed to monitor the position and the depth of the probe. Tissue necrosis of 9–12 mm is achieved using this method in a 4-min cycle. The procedure is recommended as quick, easy and feasible for outpatient settings. However, severe abdominal cramping and vaginal pain, prolonged tiredness and perimenopausal symptoms were some of the major side-effects and late complications.

Free fluid ablation (Hydrothermablator, Boston Scientific, Natick, MA, USA)

In this technique, circulating hot saline solution is instilled into the uterus under direct hysteroscopic guidance. The saline is heated to 90°C and circulated for 10 min. A randomized controlled trial comparing Hydrothermablator with rollerball ablation (Townsend et al 2003) showed similar success rates as other second-generation devices (see Figure 2.16).

Impedance bipolar radiofrequency ablation (NovaSure, Novacept, Palo Alto, CA, USA)

Bipolar radiofrequency under impedance control is used for endometrial ablation. The bipolar current provides shallower ablation in the cornual region and deeper ablation in the main cavity. The device is a three-dimensional conformable bipolar gold-plated mesh mounted on an expandable frame. After insertion, bipolar radiofrequency energy travels between the electrodes and initial electrical pulses vaporize the low-impedance endometrium. As the energy travels deeper into the muscle and begins to desiccate the superficial myometrium, the resistance grows. The system automatically terminates the procedure when an impedance of 50 ohm is reached, signifying adequate ablation.

The device can be inserted into the uterus with a cavity length between 4 and 12 mm. The mean ablation time is 90 s. Ablation is based on physical tissue characteristics and not on temperature, pressure or time. This is claimed to achieve high ablation success rates regardless of endometrial thickness. Hence, pretreatment is not necessary. The short duration of the procedure makes it feasible for use in the outpatient setting under local anaesthetic.

Efficacy was reported in two randomized controlled trials and two case series (Abbott et al 2003). Amenorrhoea rates in these four studies ranged from 41% to 59% at 12 months, with higher amenorrhoea rates in the impedance controlled procedure. Continuing menorrhagia rates ranged from 3.9%

to 14% at 12 months. There was also evidence to suggest that the majority of patients were satisfied following the procedure, and that quality of life had improved. At 3-year follow-up (Gallinat 2004), hysterectomy was avoided in 97% of women, 65% of whom were amenorrhoeic. Five-year follow-up of a randomized controlled trial comparing NovaSure and Thermachoice endometrial ablation showed that bipolar radiofrequency ablation was superior to thermal ablation (Kleijn et al 2008).

Microwave endometrial ablation (MEA, Mircosulis Plc, Waterlooville, UK)

The MEA device utilizes low-power, high-frequency microwave energy to generate heat and destroy the endometrium. The probe is inserted into the uterine cavity and moved from side to side with the temperature maintained at 75–80°C to ablate the endometrium.

MEA was compared with TCRE in a well-designed randomized controlled trial (Cooper et al 1999), and was reported to have a significantly shorter mean operative time than TCRE (11.4 vs 15.0 min, $P = 0.001$), and comparable satisfaction and acceptability. Improved quality of life 1 year after treatment was reported for both groups. These results were sustained at 2-year follow-up. At 5-year follow-up, both techniques achieved significant and comparable improvements in menstrual symptoms and health-related quality of life (Cooper et al 2005). High rates of satisfaction with and acceptability of treatment were achieved following TCRE, but these rates were significantly lower than those following MEA. The long-term data after a further 5 years of follow-up, when combined with the trial's operative findings and the known costs of both procedures, led the authors to conclude that MEA is a more effective and efficient treatment for heavy menstrual loss than TCRE (Sambrook et al 2009).

Complications of second-generation ablation devices

Minor immediate postoperative complications are common with second-generation ablation techniques and include pelvic pain, endometritis, urinary tract infection, nausea, vomiting, haematometra and pelvic inflammation. Reported serious complications included sepsis, adnexal/uterine necrosis, lower genital tract thermal injury and one death. Many of these resulted from non-compliance with the manufacturers' instructions and other avoidable factors. A 2005 update of a Cochrane review (Lethaby et al 2005) concluded that equipment failure, nausea, vomiting and uterine cramping were more likely with second-generation ablation techniques but these were less likely to be associated with fluid overload, uterine perforation, cervical lacerations and haematometra than conventional ablation and resection techniques. Overall, they compared favourably with TCRE. Most of the second-generation devices (Cavaterm, Thermachoice, NovaSure, Cryoablation) require a relatively normal uterine cavity with a depth of less than 12 cm to complete the treatment satisfactorily. Free fluid ablation (Hydrothermablator) and MEA can be performed when the uterine cavity is irregular, although complete septate or bicornuate uteri are contraindications to undertaking the procedures. Pretreatment is not generally required.

Figure 2.16 Free fluid endometrial ablation system (Boston Scientific, Natick, MA, USA).

Each device has its relative strengths and weaknesses, and no single device can be preferred over another in all circumstances. Clinicians should consider the safety and effectiveness figures, applicability to the outpatient environment, and evidence of quality-of-life improvement, applied on an individualized basis after full discussion with the patient and taking her preferences into account, as well as equipment availability and skill. Ongoing audit of a department's success rates compared with the published figures ensures that patient selection and surgical strategy are appropriate. A survey of preferences and practices of endometrial ablation/resection for menorrhagia in UK showed that second-generation devices were preferred over first-generation devices. Thermal balloon ablation was the most favoured procedure (Deb et al 2008).

Hysteroscopic Sterilization

Essure system

A safe, simple and highly effective alternative to invasive procedures for interval tubal sterilization is now possible using a hysteroscopic approach. The Essure permanent birth control device (Conceptus Inc., San Carlos, CA, USA) is a combined metallic and fibre coil placed into the cornua hysteroscopically. Approval for its use has been granted by the US Food and Drug Administration (FDA) and NICE. The dynamic outer coil made of nickel titanium alloy includes an inner flexible coil (stainless steel). The device is delivered into the fallopian tube in a tightly wound or 'low profile' position, where the two coils are tightly opposed and held in place with a wire before being released in the tubal lumen. The rapidly expanding outer coil fills the tubal lumen (Figure 2.17), anchoring the device in place. The polyethylene terephthalate fibres induce a benign localized tissue response consisting of inflammation and fibrosis, which leads to obliteration and occlusion of the tubal lumen in approximately 3 months (Valle et al 2002, Abbott 2007). The procedure is preferably done in the proliferative stage of the menstrual cycle. The procedure can be performed

under local anaesthetic (paracervical nerve block with lidocaine 1%) in the outpatient setting (Sinha et al 2007). Hysteroscopy is then performed and tubal access is established. During insertion, the microinsert is maintained in a 'wound down' configuration by a release catheter, which is enclosed in a transparent delivery catheter. A guide wire is attached to the inner coil to facilitate device placement. The device is then deployed in the proximal tubal ostium with a single-handed release mechanism, and the guide wire is detached and withdrawn. Follow-up pelvic X-ray or hysterosalpingogram is recommended 3 months after insertion to confirm correct placement of the device or tubal occlusion. An occlusion rate of 100% has been shown at the end of 1 year with no pregnancies reported (Kerin et al 2003).

A comparison of the Essure permanent birth control device and laparoscopic sterilization (Duffy et al 2005) reported reduced hospital stay, less pain, better patient acceptability, higher patient satisfaction levels and fewer adverse events with the Essure procedure. A separate study of the direct costs associated with the Essure procedure compared with laparoscopic sterilization indicated that there is a cost advantage to Essure, although indirect costs were not considered in this model (Levie and Chudnoff 2005).

Although outpatient sterilization offers many potential advantages, uptake is currently affected by cost, additional follow-up and the 3-month delay in providing permanent fertility control. Long-term results are still awaited.

Alternative techniques and future developments

The Adiana procedure (Adiana Inc., Redwood City, CA, USA and Hologic, Inc., Bedford, MA, USA) involves bipolar ablation of the proximal fallopian tube followed by the placement of a synthetic matrix, subsequently leading to tubal occlusion. The device is currently being investigated in an FDA study in the USA, Australia and Mexico (Johns 2005) (Figure 2.18).

Complications of Hysteroscopy and Procedures

Surgeon related

Inadequate training and lack of experience can lead to avoidable, but potentially major, complications, such as uterine perforation, haemorrhage and other visceral injuries.

Figure 2.17 Essure microinsert. This cross-sectional view of the uterus and fallopian tube shows the device placed across the uterotubal junction (external).

Figure 2.18 Adiana hysteroscopic delivery catheter.

Distension medium

There are different types of distension media used for hysteroscopy. Carbon dioxide may lead to gas embolism, which can lead to hypotension, tachycardia and arrhythmias, which can be fatal. Fortunately, this is a rare complication and should not occur provided the correct pressure insufflator is used.

Electrolyte imbalance from excessive absorption of non-electrolytic liquid distension medium such as 1.5% glycine can lead to hypervolaemia and hyponatraemia; a deficit of 1 l requires caution and surgery should be discontinued at 1.5 l. If the patient is asymptomatic with normal serum electrolytes and haematocrit, observation is sufficient. However, patients may develop bradycardia, hypertension, nausea, vomiting, headache, confusion, agitation and visual disturbances. This is due to water moving across the blood–brain barrier, leading to cerebral oedema. If hyponatraemia is present with haemodilution, a loop diuretic (e.g. frusemide) and restricted fluid intake may be helpful. This symptom complex has been described in the past as ‘post-TURP syndrome’ (TURP, transurethral resection of prostate). Careful assessment of fluid input and output is critical, particularly if glycine is used.

Haemorrhagic

Bleeding during hysteroscopy is caused by inadvertent trauma or by the operative steps disturbing the endometrium. Thick and vascular endometrium is likely to cause heavy bleeding. Preoperative endometrial thinning to decrease the vascularity is recommended practice. Bleeding can be controlled during surgery by coagulating the vessels under direct vision, or after surgery by inflating a Foley balloon in the uterine cavity with 5 ml of normal saline. The balloon is then deflated 6 h after surgery. If bleeding has settled, the catheter should be left in place for 1–2 h before discharging the patient. If not, the balloon can be left for a maximum of 24 h. If bleeding continues despite tamponade by the Foley balloon, hysterectomy may become necessary. In the MISTLETOE study, 1% of women undergoing endometrial resection required an emergency hysterectomy.

Bleeding is likely to occur during endometrial ablation, myomectomy, adhesiolysis and septum resection. Polyps are unlikely to bleed significantly. Arterial bleeding is pulsatile and should be stopped immediately using electrosurgery. The distension medium can suppress venous ooze. The cavity should be viewed after the pressure is reduced to check for haemostasis after operative hysteroscopy, and the hysteroscopist should always be prepared to control bleeding, which can happen unexpectedly.

Traumatic

At the beginning of any hysteroscopy, due care must be taken while grasping the cervical lip as good grip ensures that the tenaculum does not cut through. Dilatation of the cervix, if needed, is a blind procedure. If one is not careful, a false passage may be created and, occasionally, perforation of the cervical canal. This is more likely to occur when the cervix is scarred and stenosed following previous surgery, and some surgeons prefer to soften the cervix with vaginal

prostaglandins 2 h before surgery. Rarely, the dilator can give way suddenly, resulting in perforation of the fundus.

Introducing the hysteroscope under direct vision, as described above, minimizes the chance of cervical trauma or uterine perforation during introduction of the scope.

Uterine perforation

Uterine perforation occurs in approximately 1% of women undergoing endometrial ablation (Lewis 1994). It can happen due to entry of the scope into a false passage, when the scope is against the fundus, or while using the energy sources without visualizing the electrode. It is suspected if excessive bleeding is noted before the procedure is commenced, if the scope goes freely into the uterine cavity, or if the fluid distension pressure stays low or decreases suddenly. Rarely, a loop of bowel or omentum may be seen.

The energy source should only be activated while withdrawing the active tip, keeping the working element constantly under vision, which decreases the risk of perforation.

The distension medium tends to stretch the uterine wall, which is normally 2–2.5 cm thick. This has to be understood while performing operative hysteroscopy to avoid myometrial damage and decrease the risk of perforation. Extra care should be taken while operating near the uterine cornu as this is the thinnest portion of the uterine wall. Cornual injuries are likely to be full thickness with an additional risk to bladder, bowel and pelvic vessels.

As soon as perforation is suspected, the procedure should be stopped. Diagnostic hysteroscopy may be attempted, but the visualization will be poor due to inadequate distension and bleeding. Laparoscopy will help in assessment of the perforation site. The majority of injuries can be managed conservatively. In the event of heavy bleeding, haemostasis should be achieved by coagulation or by suturing the perforation. Diagnostic hysteroscopy may be completed under laparoscopic control. If perforation occurs during an operative hysteroscopy, it is wise to defer the procedure.

Infections

Diagnostic hysteroscopy is less likely to cause infection. During operative hysteroscopy, blood and tissue debris becomes a focus of infection. Energy applied to tissue leads to necrotic tissue in the uterine cavity. Infection leads to blood-stained offensive discharge, which is accompanied by fever, generally feeling unwell and raised white cell count. A high degree of suspicion in postoperative patients with deteriorating symptoms is crucial for early diagnosis. Prophylactic antibiotics should be considered for many operative hysteroscopy procedures.

Anaesthetic and energy source related

These complications are rare but still need to be discussed with patients. Patients at high anaesthetic risk will need a thorough explanation of the risks involved, and should be offered the alternative of having the procedure under local anaesthetic.

Late Complications

Infertility

Neosynechiae formation after hysteroscopic surgery may lead to Asherman's syndrome, and adhesions can reform after adhesiolysis. Infertility may persist despite treatment of the suspected cause.

Abnormal menstrual bleeding

Hysteroscopic surgery performed in the younger age group (40–45 years) is more likely to fail than that performed in older age groups. Counselling to ensure realistic postoperative expectations is crucial to improve patient satisfaction.

Pregnancy

Patients undergoing endometrial ablation should be made aware of the need to use contraception as sterility cannot be guaranteed.

Cancer

Cervical cancer is a contraindication for hysteroscopy, but endometrial cancer is not. Failure of endometrial ablation and lack of endometrial thinning despite agents (e.g. GnRH analogues and danazol) should raise suspicion. Inability to shrink a fibroid by preoperative GnRH analogue treatment is another cause for concern. There is no evidence of retrograde spread with the fluid or gaseous distension media, or of any adverse effects on the activity of the malignant cells. Similarly, histology of all specimens obtained at hysteroscopic surgery must be reviewed. Sarcomatous change in a fibroid occurs in less than 1% of patients, but must be ruled out. Endometrial chips obtained at resection may occasionally reveal malignancy.

Haematometra and pyometra

Collection of blood in the uterine cavity followed by infection can occur after hysteroscopic surgery due to cervical

stenosis. This can be prevented by avoiding ablation near the internal os. Occasionally, haematometra may occur after commencement of hormone replacement therapy (Dwyer et al 1991).

Postablation sterilization syndrome

Endometrial ablation in women with a history of sterilization can occasionally lead to postoperative pain. Active endometrium between the scarred uterine cavity and the tubal block leads to haemorrhagic tubal distension during menses. This leads to stretching of the intramural and isthmic portion of the tube with resultant pain. The presentation of this condition can be similar to an ectopic pregnancy.

Consent issues

Thorough preoperative explanation and counselling, including detailed explanation of the pathophysiology of the underlying gynaecological condition, treatment options available and their risks and benefits, is essential to ensure a successful operative experience for the patient as well as the surgeon. This is best started during the outpatient consultation when the decision for hysteroscopy is taken, and followed by giving an information leaflet with a helpline telephone number to clarify any further doubts.

Newer Developments

Diagnostic hysteroscopy is now well established in the outpatient setting in many UK hospitals. The current challenge is to extend the service to include operative work and to transfer other procedures, discussed above, from the theatre to the outpatient treatment suite. Hysteroscopy is thus becoming a skill which requires senior medical or nurse specialist input. As the number of hysteroscopies carried out under general anaesthetic declines, the importance of utilizing all training opportunities for junior medical staff cannot be overstated.

KEY POINTS

1. Hysteroscopy is a well-established tool in modern gynaecology due to its unique advantage of direct visualization of the uterine cavity.
2. Advantages include decreased morbidity and quicker recovery (for the patient), diagnosis and treatment in the outpatient department (for the surgeon), and resultant cost benefits (for the healthcare system).
3. Contraindications include cervical cancer, pelvic infection, heavy uterine bleeding, pregnancy, and inexperienced or untrained surgeon.
4. Uterine distension, essential for panoramic hysteroscopy, is achieved using media such as carbon dioxide, normal saline, Ringer's lactate, 5% dextrose, sorbitol or 1.5% glycine.
5. Pathology such as fibroids, polyps, adhesions or uterine septum can be seen and then treated using mechanical scissors, laser or electrosurgery (monopolar or bipolar).
6. Hysteroscopic myomectomy is successful in controlling menorrhagia in approximately 93% of women. Adhesiolysis leads to improved fertility in 60.5% of cases and menstruation in over 80% of cases.
7. Abnormal uterine bleeding is the most common indication for hysteroscopy. Partial or complete endometrial ablation can be performed using a resection loop, rollerball, bipolar technology or laser.
8. Endometrial ablation offers a conservative alternative to hysterectomy, although one would like to improve the current amenorrhoea rates of 15% to 40% and success rates of 70% to 75%.
9. Each second-generation endometrial ablation device has its relative strengths and weaknesses, and no single device can be preferred over another in all circumstances. Clinicians should consider the published safety and effectiveness figures, applicability to the outpatient environment, and evidence of

quality-of-life improvement before selecting which device to use in their department.

10. Preoperative endometrial thinning with danazol or GnRH analogues helps by shrinking the tissue and decreasing vascularity, thereby leading to reduced blood loss, reduced operating time and decreased fluid absorption.
11. Histological assessment of the tissue obtained at endometrial ablation, myomectomy or polypectomy is important to detect the occasional underlying malignancy or other abnormal histology.
12. Endometrial histology is also essential before any form of endometrial ablation, and is desirable for patients with postmenopausal bleeding.
13. Technological development has enabled hysteroscopy in the outpatient setting, which has led to the widespread introduction of 'one-stop hysteroscopy clinics' where patients with abnormal uterine bleeding are clerked, assessed, investigated and potentially treated in full at the same visit.
14. Other indications for hysteroscopy include infertility, foreign body and chronic pelvic pain.
15. Complications during hysteroscopy include cervical or uterine trauma, haemorrhage, infection, fluid overload, gas embolism and uterine perforation with injury to other pelvic viscera.
16. Important late complications include failure to relieve presenting symptoms, infertility, pregnancy with associated complications and cancer.
17. The above complications are rare and avoidable. However, they are potentially serious and hence the surgeon must understand the working principles of the hysteroscopic equipment, including the energy source used, and undergo a structured training programme.
18. Adequate explanation and consent improves patient satisfaction and decreases litigation when complications occur.
19. The training process includes acquiring knowledge, working on laboratory models, attending a well-recognized structured course and assisting experts. Initial procedures are undertaken under general anaesthesia, followed by daycase procedures under local anaesthesia, and finally performing diagnostic and then operative hysteroscopy in the outpatient setting.
20. Hysteroscopic sterilization using Essure is an effective method applicable to the outpatient setting, but its cost is inhibiting its widespread use.

Introduction

Laparoscopy (Greek *lapar* meaning flank) is a technique utilized by surgical gynaecologists around the world to great effect. Advances in the technique over the past two decades have revolutionized gynaecological surgery and provided a vastly improved service for patients. At the same time, some of these advances have been associated with considerable controversy, and many opinions are forcefully expressed without much factual basis. This chapter aims to discuss the basics of laparoscopy and its application, providing some of the evidence from the literature where possible.

History

Examination of the body cavities using instrumentation has been practised by clinicians over many centuries. Most of the early techniques involved inspection of the bladder and urethra (Bozzini 1805). Light sources were introduced initially with alcohol flames (Desmoreaux 1865), and subsequently the incandescent light bulb. The first inspection of the peritoneal cavity was through the posterior fornix in the early 20th Century (von Ott 1901). Examination of other cavities was described soon afterwards (Jacobaeus 1910), with carbon dioxide used for insufflation more than a decade later (Zollkoffer 1924). The first diagnosis of an ectopic pregnancy followed (Hope 1937), as did female sterilizations. Veress first reported the spring-loaded insufflation needle as a technique for introducing a pneumothorax in patients with tuberculosis (Veress 1938).

Further advances were relatively slow with few clinicians inspired by the new techniques. The first description of sterilization in English was not until 25 years later (Stephote 1967). Few therapeutic procedures were performed laparoscopically, although the technique gained widespread support for diagnosis.

The revolution in therapeutic techniques probably started with the report of the first laparoscopic hysterectomy (Reich et al 1989) and, with advances in instrumentation, light sources and camera systems, continued apace throughout the 1990s. However, a few practitioners attempted procedures that were beyond either their surgical training or ability, and responsible bodies rapidly concluded that regulation was required. The Royal College of Obstetricians and Gynaecologists (RCOG) established its training guidelines in 1994 with certification for those trained to perform at different levels. This has been repeatedly modified to bring the UK training into line with practice in other European countries.

Theatre Set-Up

When setting up a theatre for laparoscopic surgery, a number of factors need to be considered. First, both the surgeon and the assistant need to have an excellent view of the operating area. Second, the surgeon needs to be in a comfortable position, and third, the instrumentation needs to be arranged systematically and consistently.

The authors believe that the television screen should be placed between the patient's legs if the camera is inserted at the umbilicus. Figure 3.1 demonstrates that the view displayed on the screen is in the same direction in which the patient is lying and the surgeon operating. Many experienced surgeons place the television screen directly in front of themselves and behind the assistant. Under these circumstances, the surgeon is operating in a different direction to which he or she is looking; not only is this uncomfortable and ergonomically disadvantageous, but all images have to be transposed through 90 degrees, adding to the difficulties of hand-eye coordination. The additional advantage of placing the monitor between the patient's legs is that only one screen is required.

Figure 3.1 Theatre set-up is important. The monitor should be in the same plane as the surgical field, i.e. a straight line from the surgeon through the surgical field also passes through the monitor.

Figure 3.2 The patient is positioned flat on the table with legs supported. A bar is placed over the endotracheal tube to protect this from being dislodged and to support the assistant's arm.

The scrub nurse should stand in a consistent position, and instrumentation such as bipolar diathermy, scissors, graspers and suction irrigation should be placed reliably within easy reach of the surgeon. The scrub nurse should be within sight of the television screen, enabling anticipation of the next instrument required. A protective bar placed across the table prevents the assistant's arm from resting on the upper part of the patient and potentially dislodging the endotracheal tube (Figure 3.2).

Surgical Team

A coordinated surgical team is essential for safe laparoscopic procedures. An experienced anaesthetist can allow a state of permissive hypercapnia whilst the patient is in a steep Trendelenburg position. Careful positioning on a non-slip mattress decreases the tendency of the patient to slide up the bed. A well-stocked laparoscopic trolley will decrease overall operating time by minimizing the delay whilst staff find the required instruments.

Figure 3.3 A selection of trocars used in laparoscopic surgery.

Equipment

Laparoscopic surgeons are totally dependent on their equipment. Any laparoscopic procedure can only be performed safely if clear images are presented to the surgeon. The quality of the image is dependent on the weakest link in a long series of technologically advanced items. It is essential that laparoscopic surgeons are familiar with the function and adjustments of the imaging systems that they use, and it is this complicated equipment that provides the majority of the cost of laparoscopic surgery.

It is primarily the vast improvement in technology that has led to the increase in the number of procedures performed using laparoscopic techniques; however, there is scope for further improvement in laparoscopic equipment and robotics. Three-dimensional viewing systems and automated assistants may enhance the current instrumentation.

The following items are essential.

Trocars

Many different types of trocar are available, which vary in size, length and design of the tip (Figure 3.3). The 12 mm, 10 mm and 5 mm trocars are used most commonly in gynaecological surgery. When performing complicated surgery, there can be many changes of instrument down any individual port. For this reason, the trocars have to be able to grip the abdominal wall, and there are various designs to facilitate this. Some of the more modern trocars have a type of 'fish scale', whilst others utilize a screw thread which can grip more effectively but increases the diameter of the incision. The trocar tip can be conical, pyramidal or a single flat blade in design. They create different sized and shaped incisions in the fascia, with the single flat blade and conical dilating tip producing the smallest defect. Optical trocars have a blunt clear dome-shaped tip housing a crescent-shaped blade. They allow a controlled sharp dissection of the abdominal wall layers under direct vision. These trocars can be inserted prior to insufflation and may be useful in obese patients with thick abdominal walls. Trocars may be disposable or reusable. Many laparoscopic surgeons have been persuaded to use disposable trocars because of their constantly sharp tips, the so-called safety devices to retract

the tip when through the full thickness of the abdominal wall and to avoid contamination between patients. However, most surgical units find the cost of disposable trocars prohibitive for use with every case.

Laparoscopes

The laparoscopes most commonly used in gynaecological surgery are of 10 mm, 5 mm or, occasionally, 3 mm diameter. The 10 mm laparoscopes provide the largest images with the optimal illumination, although the new generation of 5 mm laparoscopes can provide an image equal to their 10 mm relatives from only a few years ago. The laparoscope is a high-precision engineered instrument which requires careful handling, both during operations and in the sterilization process between cases. It contains both a fibreoptic bundle for light transmission and a series of lenses to transfer the image back to the eyepiece. Modern laparoscopes consist of a hybrid rod lens system, although the 3 mm laparoscope utilizes a high-quality fibreoptic bundle. The hybrid rod lens system at 3 mm diameter would be too easily damaged. Most surgeons utilize a laparoscope which projects an image that appears at 0 degrees to the shaft of the scope; however, laparoscopes that project an image from 30 or 70 degrees are also available. Although these laparoscopes rarely cause problems for the surgeon, they can cause difficulty in coordination of the image by the assistant who is holding the laparoscope and camera device.

Light source and lead

The weakest link in the endoscopic equipment chain is often the light lead. This fibreoptic cable is often used for months or years after many of its cables are damaged. It also requires careful maintenance and will inevitably require replacement in time. A number of light sources exist and many surgeons still utilize the halogen system, despite the fact that this has been superseded by the more powerful xenon light source.

Camera system

Modern camera systems are an essential part of the laparoscopic surgeon's equipment. There are few surgeons around the world who continue to operate by looking directly down the eyepiece of the laparoscope, even for minor diagnostic procedures. There is a clear advantage in being able to project the image on to a television screen that is visible to all members of the surgical team. Together with the ergonomic advantages of not having to stoop over the patient, this means that camera systems are now commonplace. The image seen through the eyepiece of the laparoscope is converted into electrical signals by a charge-coupled device housed in the camera head. These electrical signals are then processed by the camera control facility which is, in turn, connected to the television monitor. Cameras may contain one or three charge-coupled devices, each of which is colour specific, recording only one of the three primary colours. Most modern camera systems enable collection of digital images which are projected on to a digital monitor, although hybrid set-ups can co-exist. Some camera heads incorporate remote buttons to allow the operator to control various features of the imaging system, such as taking prints, operat-

Figure 3.4 A sterile bag can be used for placement of the camera head and cable.

ing the video recorder or white balancing. Some cameras are autoclavable but the majority of surgeons will place the camera system inside a sterile plastic sheath before connecting to the laparoscope (Figure 3.4).

Recording equipment

The modern laparoscopic surgery theatre should contain a video recorder and still photo facility for the purpose of producing images of any procedure. Many educational and training videos have been produced and are extremely valuable. Patients may appreciate a copy of their operation and some surgeons believe it is important to create a medicolegal record of the procedure for possible future reference. There is no reason why laparoscopic surgery should be treated any differently to open surgery, and surgeons who do not record their procedures on a video can hardly be regarded as neglecting the medical records. Within gynaecology, the majority of medicolegal claims are connected with laparoscopic sterilization, and most surgeons would regard photographs of the clips occluding each fallopian tube to be a sensible precaution.

Television monitor

Many different television monitors are available, but the majority are 20 inches in size. High-definition monitors coupled with a digital camera have led to improvements in display. The monitor should be the last piece of equipment that is adjusted if the image is of poor quality, and is possibly the least important in determining a good view of the surgical field.

Insufflator

As laparoscopic surgical techniques have advanced, there has been a significant improvement in the technology of

insufflators. They should provide a maximum flow rate of approximately 35 l/min with continuous monitoring of volume, flow rate and intra-abdominal pressure. Safety devices should ensure that the maximum pressure setting is not exceeded, and most modern insufflators have an alarm to notify the surgeon. Some insufflators additionally provide smoke evacuation, either controlled by the surgeon with a foot pedal or with a direct link through to the diathermy or laser device. The insufflator needs to have simple and easily interpreted display panels. The laparoscopic surgeon will refer to the insufflator when creating the pneumoperitoneum and, at this vital part of the procedure, needs to know where to look for the information he or she is seeking.

Operating instruments

There are innumerable types of operating instruments, and individual surgeons will have their own preferences. Essentially, the instruments can be divided into the jaws, the shaft and the handles. Jaws have been designed which mimic all the instrumentation available for open surgery, plus many others. Examples are shown in Figure 3.5. The shafts may be of 10, 5 or 3 mm diameter and may or may not contain a diathermy attachment. For non-disposable instrumentation, it is often the shaft that is the most difficult part of the instrument to keep clean and maintain. Handles come in a variety of ergonomic designs, according to surgeon preference. Handles may be ratcheted or non-ratcheted in a variety of ways. Most non-disposable instruments have a detachable handle in order to convert an instrument into one with or without a ratchet. Surgeons have their favourite graspers and, as with most situations, it is more important to be familiar with an instrument and to know its limitations than it is to have a wide variety of instrumentation that is less familiar.

Laparoscopic operating equipment is expensive and has a relatively short shelf-life in comparison with open instrumentation. It is essential that any theatre budget takes this into consideration and that laparoscopic surgeons are not asked to continue working with blunt and non-functioning instruments. The more complex problems of decontamination and sterilization of these precision instruments

mean that they require careful maintenance by a specialist team.

Port Entry

A variety of techniques have been described for insufflation in order to allow the surgeon to view the pelvic and abdominal contents through the laparoscope. A great deal of discussion has occurred, particularly in medicolegal circles, regarding which is the safest technique. Complication rates for laparoscopy are so low that individual surgeons are unlikely to be able to evaluate the various entry techniques in their own practice. However, the number of laparoscopies performed is so high that the overall effect of an inferior technique could be significant for a number of patients around the country each year. Traditionally, gynaecologists are familiar with the closed technique, having performed many diagnostic laparoscopies in their training. General surgeons perform fewer laparoscopies, and these are usually for major procedures. They are usually more familiar with the open technique. Each technique has its persuasive advocates basing their arguments on a combination of scientific evidence and personal bias. Methods of port entry were examined by a recent Cochrane review which concluded that there was no evidence that one method was superior (Ahmad et al 2008).

Site of entry

There are three main sites of entry into the peritoneal cavity. The most common site is at the umbilicus, with some clinicians using a suprapubic approach and others utilizing Palmer's point (in the mid-clavicular line in the ninth intercostal space).

At the umbilicus, the abdominal wall is at its thinnest. A subumbilical incision is preferred by some clinicians, but there appears to be no logic to this. If the umbilicus is to be used, there is little point in inserting either the Veress needle or primary trocar at a point where the abdominal wall has expanded. In addition, an intraumbilical incision is cosmetically superior (Figure 3.6). The left upper quadrant of the peritoneal cavity is where the fewest intraperitoneal

Figure 3.5 A selection of laparoscopic scissors, graspers and bipolar diathermy of 5 mm diameter.

Figure 3.6 An incision is made intraumbilically.

adhesions occur. For this reason, Palmer suggested the ninth intercostal space as an insertion point for insufflation and brief inspection of the peritoneal cavity. A number of clinicians utilize this entry point when they suspect that periumbilical adhesions may be present.

Closed laparoscopy

A vertical incision is made intraumbilically, with the angle of the Veress needle insertion varying according to the body mass index (BMI) of the patient, from 45 degrees in non-obese women to 90 degrees in obese women (Figure 3.7). Most clinicians stabilize the anterior abdominal wall by grasping it with the left hand, while the right hand inserts the Veress needle. Experienced laparoscopists can feel the Veress needle pass through the layers of the anterior abdominal wall, and will usually be able to tell whether the Veress needle is correctly positioned. At this point, a number of techniques have been described to assist in demonstrating that the Veress needle is correctly positioned. A syringe can be used to aspirate from the Veress needle to identify visceral contents. Alternatively, a droplet of water or saline can be placed on the end of the Veress needle and the negative intra-abdominal pressure causes this to be sucked in. A syringe placed on the end of the Veress needle and containing water or saline, but without its plunger, will usually allow the solution to drip into the peritoneal cavity if correctly positioned. Once insufflation is commenced, the filling pressure can be observed and uniform distension of the abdominal cavity can be determined by percussion. In particular, the area over the liver becomes resonant to percussion when pneumoperitoneum is created. 'Wagging' of the Veress needle from side to side should be avoided as this can enlarge a 1.6 mm puncture injury to an injury of up to 1 cm in viscera or blood vessels.

It is important to create pneumoperitoneum of a set pressure rather than volume. The size of the intraperitoneal cavity varies greatly between individuals. The purpose of insufflation is to provide a cushion between the anterior abdominal wall and the important underlying structures when the primary trocar is inserted. Phillips et al (1999) demonstrated that an intraperitoneal pressure of 25 mmHg

was necessary in order to maintain the gas bubble during insertion of the primary trocar. It is extremely important that this pressure is then reduced to 15 mmHg or less for the rest of the operation. Ventilation difficulties are not encountered at this initial filling pressure, as the patient is flat and the pressure of this level is only maintained for a short period of time.

Direct entry

Direct trocar insertion without pneumoperitoneum using an optical trocar can be employed but there is insufficient evidence to suggest any benefit over the open or closed techniques (Ahmad et al 2008). A disadvantage of this technique is that any inadvertent visceral perforation is guaranteed to be of significant size, unlike damage caused by the Veress needle. Direct entry is increasingly employed in the morbidly obese undergoing gastric bypass surgery.

Open laparoscopy

The Hasson entry technique was first described in 1971 (Hasson 1971). A vertical incision is placed intraumbilically and the various layers of the abdominal wall are incised using two Langenbeck retractors on either side to assist with visualization. Once the rectus sheath is incised, a suture is inserted on either side of the incision into the sheath. The peritoneum is opened, a blunt Hasson cannula is inserted directly into the peritoneal cavity and insufflation is commenced. A seal is usually created utilizing the sutures in the rectus sheath and tightening around a cone attached to the Hasson cannula.

Comparison of complications

A vast number of laparoscopies using the closed technique have been performed over many years. A collection of over 350,000 procedures has calculated the risk of bowel damage to be 0.4/1000 and the risk of major vessel injury to be 0.2/1000. The most common bowel injury is to the transverse colon, while the most common vascular injury is to the right common iliac artery (Clements 1995).

There are no comparable data on such a large number of patients for open laparoscopy. One rationale of the Hasson technique is to identify intraperitoneal and bowel adhesions at entry into the peritoneal cavity, thus avoiding blind insertion of a trocar into a visceral structure, but this was not supported by a recent Cochrane review (Ahmad et al 2008). More logically, the Hasson technique avoids major vessel damage. Population-based studies are an inappropriate way of comparing the two techniques, as many clinicians only use the open laparoscopy approach if they think there is a danger of intraperitoneal adhesions. They are therefore selecting a high-risk group of patients on which to perform this technique. Studies that have been published with large numbers suggest that bowel damage in the open laparoscopy group is equivalent to that in the closed laparoscopy group (Chapron et al 1998).

Advocates of the open laparoscopy approach maintain that the time taken to achieve pneumoperitoneum is equivalent to that of the closed laparoscopy approach (Pickersgill et al 1999).

Figure 3.7 The Veress needle is placed intraumbilically and directed towards the pouch of Douglas during insertion.

Ten percent of patients will have intra-abdominal adhesions, with 5% having severe adhesions containing bowel around the umbilicus. Ninety-two percent of these patients with severe adhesions will have had a previous laparotomy, with the vast majority following midline incisions (Garry 2000). Although not all visceral perforations caused by laparoscopy are the result of negligence, it would seem prudent for clinicians to take previous midline laparotomies into consideration when performing a laparoscopy. It is important that those advocates of closed laparoscopy are able to perform open laparoscopy when their own technique fails. There is currently no conclusive proof that one technique is safer than the other, and a huge randomized controlled trial would be necessary to detect small safety differences between the two techniques.

Teaching and Learning

The RCOG recognized at an early stage that teaching and learning laparoscopic surgery was important for safe practice. A system of recognized preceptors who are qualified to teach laparoscopic techniques has been established and is maintained by the RCOG. This is an area which is currently in a state of flux. The RCOG has recently developed a basic surgical skills course and an advanced training skills module in benign gynaecological laparoscopy. Achievement of the module requires proficiency in oophorectomy, ovarian cystectomy and treatment of peritoneal and ovarian endometriosis. Other units around the country have set up courses such as the University of Surrey's MSc which teaches skills for treating complex endometriosis.

Many trainers have recognized the value of simulating exercises in the training of laparoscopic surgeons, so laboratories have been established to teach and assess practical skills in a variety of centres around the country. Hand-eye coordination exercises are now widespread and many are quite imaginative. Computer simulations play an increasing part in the training of laparoscopic surgeons. Exercises based on surgical procedures are available through the i-sim® system (www.isurgical.com). Simulators have been shown to improve surgical performance whilst learning a new technique (Aggarwal et al 2006). It is perfectly logical to assume that, in the future, surgeons will have to demonstrate their competence on these virtual reality systems before being allowed to operate on patients. Reproducible tests of dextrous ability can be used as part of the assessment process when determining which candidate should be appointed to a particular specialty post.

Laparoscopic suturing

Laparoscopic suturing can be avoided in many procedures, but is an important skill for the advanced laparoscopic surgeon. Many experienced open surgeons are reluctant to pass through the sometimes humiliating learning curve required in order to master suturing techniques. However, it is simply a matter of 'practice making perfect' and laparoscopic suturing is an ideal exercise for the simulator.

Sutures are usually introduced through the accessory ports, and care needs to be taken to ensure that the needle is observed for the entire time it is in the peritoneal cavity.

Laparoscopic suturing is less forgiving than suturing at open surgery, and this is classically demonstrated with the curved needle. The correct surgical technique is to insert the tip of the needle into the tissue and then rotate the needle through the tissue in an arc that follows the exact curve of the needle. The needle holder needs to be at right angles to the needle in order to fulfil this task. Poor surgical technique at open surgery often involves surgeons pushing a curved needle in a straight line through the tissues, rather than rotating it through.

Some surgeons prefer to use a straight needle when suturing laparoscopically as this passes through the ports more easily. The principle of suture insertion remains the same by passing the needle through the tissues in a direction that mimics the shape of the needle.

Once the suture is appropriately placed, a knot can be tied either intracorporeally or extracorporeally, according to the individual surgeon's preference and familiarity. Knots of adequate strength can be tied by either method.

Pre-tied sutures

The endo-loop is a simple technique for applying a suture to a pedicle, pushing down a pre-tied knot (Figure 3.8). These pre-tied sutures employ a Roeder knot and are extremely useful either as a time-saving device or for less-experienced laparoscopic surgeons.

Stapling

Mechanical stapling devices have helped to revolutionize laparoscopic surgery and encouraged a generation of surgeons to utilize these precision instruments (Figures 3.9 and 3.10). The device usually inserts three lines of carefully arranged titanium staples, either side of a knife tract, which allows the tissue to be divided when the staples are fired. It is an extremely efficient and rapid instrument, but its major disadvantage is its diameter which requires a 12 mm port. They do need to be applied with great care, and the surgeon needs to ensure that only the desired tissue is secured within the jaws of the device. In the use of this instrument, the surgeon has to be particularly aware that the view on the

Figure 3.9 The stapling device. The white handle is fixed, the grey lever closes the instrument and the black lever fires the staples and knife.

Figure 3.10 The cartridge of the stapling device shows six rows of titanium staples separated in the centre by the knife tract.

monitor is only provided in two dimensions. The tips of the stapling device must be visualized before firing.

Specimen removal

Many laparoscopic operations are initially straightforward, such as an oophorectomy for a large ovarian cyst. Very often, the most difficult part of the procedure is actually removing the specimen without increasing the size of the incisions in the abdominal wall. A number of devices have been employed in order to make this extraction easier. The most commonly used specimen retrieval system utilizes a bag such as the Endo-catch bag in Figure 3.11. The bag comes pre-folded and springs open once inserted into the abdominal cavity, allowing the specimen to be inserted. The edges of the bag are brought to the surface and the specimen removed without spilling its contents into the peritoneal cavity. A large cyst can be deflated extracorporeally for easy removal.

For larger cysts and more solid structures, such as fibroids, alternative methods of specimen removal may be necessary. A posterior colpotomy can be extended with ease to 4 or 5 cm diameter without increasing discomfort or recovery

Figure 3.11 The bag specimen retrieval system. Advancing the white plunger pushes the bag out of the introducer. The wire around the neck of the bag springs open.

time for the patient. Large-volume specimen bags can be inserted through the posterior fornix and wrapped around large ovarian cysts or fibroids. The neck of the bag can be brought through the incision in the posterior fornix, and the specimen either morcellated or deflated through a much larger incision than is required for the abdominal ports. Figures 3.12–3.20 demonstrate the removal of a 7 cm pedunculated fibroid using a posterior colpotomy. Initially, the fibroid is fixed with a suture to avoid it being displaced into

Figure 3.12 This uterus has a pedunculated 7 cm fibroid arising from the left side of the fundus. An instrument can be seen causing an indentation in the posterior fornix.

Figure 3.13 A suture has been introduced through the posterior fornix and is passed through the fibroid to fix the specimen.

Figure 3.14 The suture is returned to the posterior fornix.

Figure 3.15 A staple is placed over the pedicle of the fibroid which is divided.

Figure 3.16 The staple provides an effective haemostatic and excisional device. Despite the patient being in a steep Trendelenburg position, the separated fibroid remains fixed by the suture through the posterior fornix.

Figure 3.17 The view vaginally shows the suture passing through into the peritoneal cavity.

Figure 3.18 The incision in the posterior fornix is enlarged to 3–4 cm.

Figure 3.19 The fibroid is morcellated and removed through the posterior fornix incision.

Figure 3.20 Although morcellated, the fibroid is completely removed without the need to extend the abdominal incisions.

the upper abdomen under the influence of gravity once it is disconnected from the uterus (Figures 3.13–3.14). A straight-forward Endo-GIA staple disconnects the fibroid from the uterus and the fibroid is brought down to the posterior colpotomy by pulling on the suture (Figures 3.15–3.17). Transvaginally, the posterior colpotomy is extended and the fibroid morcellated to remove the specimen (Figures 3.18 and 3.19). The posterior colpotomy is repaired either vaginally or laparoscopically with precision.

Mechanical morcellators are an alternative way of removing the fibroids or the fundus and body of the uterus if a subtotal hysterectomy is performed. Extreme care needs to be taken with mechanical morcellators as they are dangerous if the wrong tissue is grasped inadvertently. They require considerable patience and are another piece of expensive theatre equipment.

Energy sources

Many energy sources are available for use with laparoscopic instruments. Bipolar and monopolar diathermy are widely available and reliable. The use of lasers is covered elsewhere in this text (see Chapter 4). Newer methods of tissue division and vessel sealing include the Harmonic Scalpel® and the Ligasure® system. Progress in this area of technology has allowed many diagnostic laparoscopies to be converted into effective therapeutic treatment.

Gasless laparoscopy

It is possible to operate within the peritoneal cavity without distending it using carbon dioxide (Chin et al 1993, Wood et al 1994). A rigid mechanical support is required in order to elevate the anterior abdominal wall so that the viscera can be identified. The advantages of gasless laparoscopy are the avoidance of insufflators causing possible gas emboli, and the use of simpler trocars. However, most gasless laparoscopy techniques require extra portals in order to insert the mechanical device for visualization. It is not a technique that has become widespread.

Robotic techniques

Robots were first used in humans to carry out a transurethral resection of the prostate in 1991 at Imperial College, London (Davies et al 1997). The controls of modern robots have an intuitive ease of use, and complex manoeuvres such as suturing can be easily mastered. Physiological movement can be digitally subtracted from the camera signal to give a still image on the screen; for example, cardiac pulsation can be dampened down. The surgeon can be remote from the patient, even in another continent. In an era of consumer-driven health care, there is increasing demand for the most up-to-date equipment. Disadvantages of the robot include limited haptic feedback so the operator is unable to gauge the force applied to the tissue. The robot is an expensive and complex piece of equipment requiring careful maintenance, and in the event of a malfunction, the surgeon must be prepared to complete the operation either laparoscopically or as an open procedure. Operations performed robotically include radical prostatectomy, beating heart bypass grafts and radical hysterectomy.

Complications of Laparoscopy

The complications associated with port entry have been mentioned earlier in this chapter, and this is generally the most dangerous time for the patient. However, laparoscopic surgery can have many of the same complications as open surgery, depending on the complexity of any procedure. A list of possible complications is seen in Box 3.1.

Once access has been obtained and the laparoscope inserted, accessory ports have to be placed. These need to avoid the inferior epigastric vessels which supply the anterior abdominal wall. They can invariably be visualized even in the most obese of patients by remembering that they originate from the external iliac vessels as they enter the femoral canal, and then run laterally to the obliterated umbilical vessels. The authors usually place a left accessory port lateral to the inferior epigastric vessels and a further port suprapubically. This allows the right-handed surgeon to operate in a straight line whilst opposing the instruments sufficiently for them to work together. Placing the right port lateral to the inferior epigastric vessels means that the surgeon will have to reach over the patient to an instrument that is then aimed back towards the pelvis. This position is uncomfortable for long procedures.

Once the accessory trocars are inserted, complications will depend on the procedure and will be similar to open surgery. During steep Trendelenburg tilt, the pressure required to ventilate the patient will increase and carbon dioxide absorption can be a problem in those with borderline pulmonary function. As with any type of surgery, trust and

understanding between the anaesthetist and the surgeon are essential.

Damage to visceral structures can occur during any procedure, but they can be more difficult to recognize with laparoscopic surgery. Dense adhesions may involve the bowel and therefore the use of diathermy should be limited. Inadvertent diathermy damage by direct current transfer, or direct or capacitive coupling may occur.

Postoperatively, patients should be more mobile and make a quicker recovery as a result of smaller abdominal wounds. Serious complications such as unrecognized visceral injury may occur in the first few days and it is essential that these are rectified immediately. All surgeons get complications and any surgeon who does not believe it possible that their patient could sustain a complication from a laparoscopic procedure is a potentially dangerous surgeon. As a general rule, all patients should continue to improve from 24 h after any laparoscopic procedure. If this does not occur, consideration should be given to intraoperative visceral injury, and the patient should be investigated further with possible return to theatre before they collapse.

Medium- and long-term laparoscopic complications are rare. Incisional hernias have been reported, particularly in slim patients where larger (10–12 mm) ports are used lateral to the rectus muscle. These can usually be avoided by closure of the rectus sheath and ensuring that when removing the primary trocars at the same time as the pneumoperitoneum, no omentum has been drawn into the wound.

Uses of Laparoscopy

Diagnostic

All gynaecologists perform diagnostic laparoscopies for multiple indications. It is a common investigation for pelvic pain, infertility, assessment of pelvic masses and in trials to assess clinical efficacy of treatment. There is virtually no indication for a diagnostic laparotomy in current medical practice. All clinicians would agree that a diagnostic laparoscopy is a quick, easy and safe way of assessing the peritoneal cavity, while causing minimal discomfort and allowing rapid recovery for the patient.

Therapeutic

If a therapeutic laparoscopic procedure can be performed with ease and without putting the patient in increased danger, there is no question about its efficacy. Clinicians would agree that a diagnostic laparotomy is unnecessary, has a long recovery period and significant minor morbidity. It is therefore logical to extend this principle into the area of therapeutics. There are many procedures that are clearly better performed laparoscopically, and these should be made available to all patients. It is the responsibility of health authorities, hospital administration and local clinicians to ensure that this logical and sensible approach is available for their patients. Examples of procedures that should normally be performed laparoscopically are given in Box 3.2.

Obese and infirm patients recover significantly better after a laparoscopic procedure compared with an open procedure. A high BMI, previously regarded as a relative

Box 3.1 Complications of laparoscopy

Primary trocar insertion

Bowel injury: transverse colon, small bowel
Vessel injury: common iliac arteries or veins, aorta, inferior vena cava
Bladder perforation
Damage to omentum
Surgical emphysema from extraperitoneal gas
Vasovagal reflex during gas insertion
Gas embolism

Secondary trocar insertion

Inferior epigastric vessel injury
Bowel injury

During the procedure

Anaesthetic complications: ventilatory problems, CO₂ absorption
Visceral injury: recognized, unrecognized, direct, secondary to diathermy, etc., contamination of operative field
Haemorrhage: circulatory compromise, visual loss
Equipment failure: cameras, lighting, diathermy, staples, sutures, etc.

Postoperative

Fluid balance
Pain relief
Thromboembolic
Unrecognized visceral injury
Port site hernia

Box 3.2 Therapeutic procedures that should routinely be performed laparoscopically

Laser ablation of endometriosis (Sutton et al 1994)
 Salpingectomy (Yao and Tulandi 1997)
 Removal of ovarian cysts (Audebert 1998)
 Minor adhesiolysis
 Sterilization

contraindication, should be viewed as an indication for a laparoscopic approach.

The debate about laparoscopic surgery becomes more involved when examining more complex gynaecological procedures. There is no doubt that the vast majority of procedures can be performed laparoscopically, but not all procedures should be. The dilemma is in determining which patient fits into which category, and that will sometimes depend on the surgeon. This is not the place to discuss at length the use of laparoscopy in various operations. Laparoscopy is merely the route by which a procedure is performed. It is the appropriate operation rather than the route that is perhaps more important.

The debate concerning the route most suitable for a hysterectomy is an excellent example of the difficulties in determining where laparoscopic surgery is best used. For many years, the surgeon has had a choice of the vaginal or the abdominal route for removing a patient's uterus. The rates of vaginal hysterectomy vary enormously depending on the country in which a patient is treated. However, the circumstances in which a vaginal or abdominal hysterectomy is most suitable are still unclear.

The frequently quoted paper from Dicker et al (1982), where one-third of hysterectomies were performed vaginally, demonstrates a faster recovery time and lower minor morbidity rate by this route. Major morbidity was infrequent in both groups, but considerably higher in the vaginal hysterectomy group. It seems logical that an easy vaginal hysterectomy would have minimal major complications and provide the patient with the shortest recovery period. However, as the procedure becomes more difficult, the possibility of major complications increases. Judging when to dismiss the advantages of shorter recovery and look for the lower major morbidity rate is an issue that has not been standardized.

It is most desirable to perform a vaginal hysterectomy under the easiest circumstances, but when the procedure is extremely difficult, an abdominal hysterectomy is preferable. At some point between these two extremes, the lines cross.

Laparoscopic hysterectomy was introduced in an attempt to make some of the more difficult vaginal hysterectomies easier. As a consequence, many patients who would have otherwise had an abdominal hysterectomy were offered a laparoscopic hysterectomy or a laparoscopic-assisted vaginal hysterectomy. The effects of the route of hysterectomy were examined in 1347 women in the eVALuate study (Garry et al 2004). The trial had two arms; one arm compared abdominal with laparoscopic hysterectomy, and the second underpowered arm compared vaginal and laparoscopic routes. The abdominal arm showed a higher risk of complications including ureteric injuries and conversion to laparotomy with the laparoscopic route, but also less pain and a shorter hospital stay. The vaginal arm showed a longer duration of operation with the laparoscopic route compared with the vaginal route. The trial has been criticized for the low number of laparoscopic hysterectomies performed by each surgeon. The complications may have been higher due to the learning curve of the surgeons. In addition, conversion to open surgery was recorded as a major complication, which may have encouraged surgeons to persist against their better judgement.

With a decrease in the number of hysterectomies being performed and significantly reduced surgical experience as a trainee, the opportunity to learn these techniques is limited. The vast majority of gynaecologists performing this surgery are inevitably self-taught. There are no scientifically reproducible data to show which factors should determine whether a patient has a vaginal, laparoscopic or abdominal hysterectomy. Indeed, the indications would be different for individual surgeons with varied surgical expertise; as such, the debate continues.

There will obviously be some instances where one procedure is clearly preferable. Where prolapse exists, a vaginal hysterectomy is preferable. Where multiple intraperitoneal adhesions are expected or ovarian malignancy is diagnosed, an abdominal approach is superior. For most stage I endometrial cancers where the peritoneal cavity needs to be inspected, washings taken, ovaries removed and possibly lymph node sampling performed, a laparoscopic hysterectomy is superior.

As with the majority of situations, the real truth lies somewhere between the two extremes. Clinicians who have avoided learning laparoscopic surgical techniques need to accept that they have significantly improved the care of many patients and should be readily available. Conversely, some of the proponents of laparoscopic surgery need to accept that there is nothing clever about a procedure that results in increased serious morbidity.

KEY POINTS

1. As a result of smaller incisions, uncomplicated operations performed laparoscopically result in faster recovery and less postoperative pain.
2. The equipment required for laparoscopic surgery should be of good quality and well maintained.
3. Systematic training of surgeons is required using courses, simulators and a log of the case load.
4. The single most dangerous time in any laparoscopic procedure is usually the insertion of the primary trocar. An understanding of anatomy and surgical principles is necessary in order to minimize the risk.
5. Various techniques are available to make laparoscopic surgery easier. These include staples, pre-tied knots, specimen retrieval bags and robots.
6. Virtually all operations can be performed laparoscopically, but not all should be.

INTRODUCTION	48	CONCLUSIONS	58
DIATHERMY	48	KEY POINTS	58
LASERS	52		

Introduction

For many years, diathermy was the technique of choice for tissue resection and destruction in both gynaecology and general surgery. The advent of the laser in the 1960s threatened this supremacy, but, during the last decade, advances in diathermy have led to a more balanced position between the two modalities. The aim of this chapter is to briefly explain the operation of these instruments, tissue effects, common system types, some of the safety aspects involved and practical clinical use of both techniques in gynaecology.

Diathermy

Diathermy has been used in surgical procedures for over 100 years (d'Arsonval 1893) for cutting and coagulation of tissues. Harvey Cushing pioneered the use of electrosurgery in neurosurgery, using a generator designed by Bovie in the 1920s, and this name is still synonymous with diathermy to some surgeons.

Although diathermy is still a much-used tool in surgical practice, few surgeons have received formal training in its use. Operating theatres will often have a variety of diathermy units for which 'standard' settings are used without reference to the operating conditions. In conventional open surgery, this has only presented a few hazards. The development of laparoscopic and hysteroscopic surgery has greatly increased the number of applications for electrosurgery and has presented new dangers. Only by having an understanding of the principles of this energy source will surgeons avoid the risk of injury to the patient, theatre staff and themselves.

Electrosurgery refers to both types of diathermy, monopolar or bipolar, in which current passes through the patient's tissue. In monopolar diathermy, the active electrode and return electrode are some distance apart. In bipolar diathermy, the two electrodes are only millimetres apart. Electrocautery refers to the use of a heating element in which no current passes through the patient.

Monopolar diathermy

In monopolar diathermy, one electrode is applied to the patient who becomes part of the circuit. The surface area of the electrode plate is much greater than the contact area of the diathermy instrument to ensure that heating effects are confined to the end of the active electrode (Figure 4.1). The advantage of monopolar diathermy is that it can be used to cut as well as to coagulate tissues.

Tissue effects of diathermy

When household electrical current of 50 Hz frequency passes through the body, it causes an irreversible depolarization of cell membranes. If the current is sufficiently large, depolarization of cardiac muscles will occur and death may result. If household current is modified to a higher frequency, above 200 Hz, depolarization does not occur; instead, ions are excited to produce a thermal effect. This is the basis of diathermy. Figure 4.2 illustrates how the frequency of a current influences the effects on the body.

Factors which influence the effect of diathermy

- Diathermy current
 - Current density
 - Size of the current
- Current waveform
 - Cutting and coagulation current
- Type of tissue
 - Tissue moisture
- Duration of application
- Size and shape of diathermy electrode

Diathermy current

The amount of damage or thermal injury that diathermy produces is determined by the current density and the size of the current.

Figure 4.1 Monopolar and bipolar diathermy systems.

Figure 4.2 Current frequency spectrum.

The current density at the tip of a needle electrode will be very high because the current is concentrated into a small point. The plate used for the return electrode in monopolar diathermy has a large surface area of contact, resulting in a much lower current density. Any thermal effect will therefore be widely dissipated. This highlights the need for the whole surface of the plate to be attached securely to the body. If the plate becomes partially detached, the current density will be greater in the remaining attached part and a burn may result.

The size of the current is influenced by the voltage potential and the resistance to current flow according to the following equation:

$$\text{Current (amps)} = \frac{\text{potential (volts)}}{\text{impedance or tissue resistance (ohms)}}$$

Turning up the power output of an electrosurgical unit will increase the size of the diathermy current if the resistance remains constant. Some electrosurgical units can automatically alter the voltage potential to keep the current constant if the resistance changes; however, an alternative design

Figure 4.3 Cutting and coagulation waveforms.

approach allows for control of this voltage (voltage regulation).

The resistance of tissue varies particularly with its water content. Dry tissue has high resistance and moist tissue has lower resistance. Thus, during diathermy of an area of tissue, it is desiccated by the thermal effect and its resistance will increase. To prevent the current flow from falling, some modern electrosurgical units will increase the voltage output. The surgeon should be aware of this because there are additional hazards to working with higher voltages. Insulation failure, capacitance coupling and direct coupling are all more likely with a higher voltage.

Cutting and coagulation

Coagulation and cutting can be achieved by changing the area of contact or the waveform of the current. The cutting waveform is a low-voltage, higher frequency current but the area of contact is the main factor and a cutting effect is achieved when the cutting electrode is not quite in contact with the tissue so that an electrical arc is formed. This causes the water in the cells to vaporize and the cells to explode as they come into contact with the arc. The power and current levels will rise when cutting takes place inside a liquid-filled, relatively non-conductive cavity such as the bladder or uterus. The surgeon must be aware that if the resistance increases when using cutting current (e.g. when cutting through the cervix with a wire loop), some generators will produce a higher voltage to maintain current flow against the increased resistance.

When the electrode is brought into direct contact with tissue and the waveform is modulated, coagulation occurs rather than vaporization. An intermittent waveform is used and thus bursts of thermal energy are interspersed with periods of no energy (Figure 4.3). For the power delivered to the tissue to remain constant, the electrosurgical unit must deliver a higher voltage to compensate for the episodes when no energy is delivered (up to 90% of the time with pure coagulation current). Thus, whilst cutting current at 50 W power will produce a high-frequency current of approximately 200–1000 V, a coagulation current may produce over 3000 V to deliver the same wattage to the tissue. The coagulating effect is produced by slower desiccation and shrinkage of adjacent tissue, producing haemostasis. The higher voltage produced by coagulation current carries a higher risk of inadvertent discharge of energy.

If a mixture of the two types of waveform is employed, the advantages of both techniques are exploited. This is normally termed 'blended' output and many combinations are possible.

Type of tissue

Tissue moisture is the major factor affecting tissue resistance; the higher the moisture content, the lower the resistance and the higher the current flow. The cervix in a postmenopausal woman will have lower water content than that of a young nulliparous woman. A lower wattage will be required to perform a loop biopsy in the latter case.

Duration of application

The longer the duration of application of electrosurgical current, the greater the extent of thermal injury. Research on uterine tissue shows that the duration of exposure of the tissue to current, rather than the wattage used, was the most important factor in producing tissue damage (Duffy et al 1991).

Size and shape of the diathermy electrode

The smaller the point of contact, the greater the current density. Thus, if the points of diathermy scissors are brought close to tissue, a cutting effect will result, whilst if the convex part of the scissor blades is used, a lower current density will result in a coagulating effect. Similarly, when using a wire loop to biopsy the cervix, the thickness of the wire or the diameter of the loop will influence the current. A thicker wire will need a higher current than a finer wire to produce a cutting effect because of the lower current density.

Heat and tissue injury

Diathermy current produces thermal injury to tissues. The temperature generated will dictate the degree of injury (Table 4.1). If carbon is seen on the tip of the diathermy electrode, the surgeon can assume that, at some stage, a temperature of 200°C has been reached.

Bipolar diathermy

In bipolar diathermy, the current flows between two electrodes positioned a short distance apart because both contacts are on the surgical instrument. Lower power is employed since high power would damage the tips of the instrument. This is safer because the current flow is limited to a small area and lower power is used, but a cutting effect cannot be achieved. These features encourage some surgeons to employ bipolar diathermy exclusively in the laparoscopic environment. However, there is still a small risk of aberrant current flow because the patient, table and diathermy machine are all earthed. In addition, the tissue temperatures

are much higher (340°C) and this factor alone can cause unexpected effects.

Bipolar current produces tissue desiccation and has been used commonly in tubal sterilization. More recently, in laparoscopic surgery, its value in coagulating major vascular pedicles has led to its use in laparoscopic hysterectomy and laparoscopic salpingectomy for ectopic pregnancy. The lower power employed also leads to less heat spread to adjacent tissues, which reduces the risk of injury to nearby delicate structures. Engineers are endeavouring to produce reliable bipolar dissectors and scissors to compete with the range of monopolar diathermy instruments available.

Instruments are now available which coagulate a pedicle with bipolar current and utilize a non-electrosurgical blade to cut the pedicle. These instruments are often referred to as tripolar instruments, although this is a misnomer.

Bipolar instrumentation has also been introduced into hysteroscopic surgery. A bipolar electrode may be employed in the outpatient setting for the removal of endometrial polyps. The distension medium used with these devices is saline rather than glycine. Saline is isotonic and therefore reduces the risk of fluid overload associated with a hypotonic solution such as glycine.

Short-wave diathermy

Electrode redesign has led to an interest in the use of short-wave diathermy for its tissue destructive effect (Phipps et al 1990). It has been used in endometrial ablation. In this, the two electrodes form a capacitor in the output circuit with the patient providing the dielectric medium between the two plates. Frequencies of approximately 27 MHz are employed with power levels of approximately 500 W. By altering the shape and size of the electrodes, heating effects may be localized or diffused as required. However, care must be exercised as the effects are not always predictable.

Diathermy safety

Three major safety issues with the use of monopolar diathermy have become apparent with the evolution of electrosurgery in laparoscopic surgery. Each of them involves inadvertent discharge of diathermy current. These issues are:

- insulation failure;
- direct coupling; and
- capacitive coupling.

Insulation failure

Defects in insulation are most likely to cause a discharge of current when higher power is employed. The use of coagulation current carries a greater risk than cutting current. Insulation failure can occur at any point from the electrosurgical unit to the active electrode. The most common site of failure is in the instrument that contains the active electrode. With conventional surgical instruments, the most common site is the joint on diathermy graspers where repeated use wears away the insulation material. Any insulation breakdown, seen as sparks from the joint area, is usually clearly visible because the whole instrument is within the surgeon's field of view. This contrasts with laparoscopic surgery where the field of view is much smaller and only a small part of the

Table 4.1 The degree of injury caused at different temperatures

Temperature (°C)	Tissue effect
44	Necrosis
70	Coagulation
90	Desiccation
200	Carbonization

instrument containing the active electrode may be visible. Repeated discharges from a break in the insulation may occur without the surgeon being aware. Damage to insulation most commonly occurs when moving an instrument through the laparoscopic port. Although the port valve may cause damage, the most likely cause is scraping against the sharp edge of the inner end of the port, particularly one constructed of metal.

Concern about insulation failure has fuelled the debate about disposable and reusable instruments. Disposable instruments clearly have an advantage in that the insulation sheath does not have to withstand both repeated use and repeated cleaning cycles. However, disposable instruments are built to much less robust specifications and the insulating material may not withstand harsh treatment in a long case. It is important that surgeons and theatre nurses are constantly vigilant for evidence of trauma to insulation, and reusable instruments must be checked on a regular basis both during and between cases.

Whilst a metal port may cause more trauma to the instruments passing through it, it will allow discharge of diathermy current in the event of insulation failure. The large area of port contact with the skin should enable the current to be dissipated without serious thermal injury. A plastic port would not facilitate such a discharge and the current might therefore flow to adjacent bowel, causing damage that may not be recognized at the time. Sigmoid colon is the most vulnerable piece of bowel because of its proximity to a left lateral port. If a metal port cannula is used, a plastic retaining sleeve must not be used because this prevents any discharged diathermy current passing through the skin back to the ground plate.

Direct coupling

Direct coupling involves the transmission of diathermy current from one instrument to another. Many surgeons use direct coupling to coagulate small vessels which have been grasped with a small forceps, when opening a wound for example. The diathermy instrument is then placed against the small forceps and the pedal pressed. Such a practice carries a real risk of a diathermy burn to the surgeon or assistant. If the surgeon's glove has a perforation, the diathermy current may flow through the surgeon to ground either through the feet or through contact with the operating table. The surgeon should also be aware that theatre gowns do not provide insulation against high-frequency diathermy current.

The risk of direct coupling will be reduced in laparoscopic surgery if insulated instruments alone are used when diathermy is employed. Since many instruments, such as needle holders, are not commonly produced with insulation, this may restrict instrument choice. The risk of direct coupling to a metal port is increased when the working part of the laparoscopic instrument is large. The surgeon must always try to keep the whole of the metal part visible when using diathermy so that any inadvertent discharge will be seen.

Capacitive coupling

The concept of capacitive coupling is new to most gynaecologists. A capacitor consists of two conductors separated by an insulator. A metal instrument surrounded by an insu-

lated sheath passing through a metal port is a capacitor. When a current passes through the instrument, a capacitive current may develop in the metal port, particularly if it is insulated from the skin. The higher the current passing through the instrument, the greater the capacitive current. If the port is insulated from the skin (by a plastic sleeve), capacitive current may be discharged to adjacent bowel, causing thermal injury. In common with insulation failure, the sigmoid colon is most vulnerable to capacitive current injury due to its proximity to a left lateral port.

A capacitive current can also develop in a gloved hand holding a non-insulated instrument through which diathermy current is passed. This risk is greater if the hand is moist and there is contact between the surgeon and the operating table or the floor.

Other safety issues

Current flow to adjacent organs

The current will follow the path of least resistance, and, if a non-target tissue such as bowel lies in contact with target tissue, the current will flow through the tissue with least impedance. In addition, the impedance will rise as the target vessels desiccate, and the current may then flow to an alternative earth, usually but not necessarily in contact with the pedicle. If the current flows through bowel, damage will result which may not be recognized at the time.

Surgical clothing

Operating theatre gowns do not provide insulation against high-frequency electrosurgical currents. This means that there is always a risk of discharge of electrosurgical current through to the operating table.

Operating theatre footwear used to provide 'antistatic' protection. Antistatic theatre shoes were used to prevent build-up of static electricity, which could spark and ignite volatile anaesthetic gases. Since such agents are no longer employed in anaesthesia, there is no need for antistatic footwear. Non-antistatic footwear will generally provide higher resistance between the surgeon and ground, and will therefore reduce the risk of discharge through the surgeon to ground.

Electrosurgical unit

The surgeon should be familiar with the electrosurgical unit in the theatre. Many departments have different units available with different settings and features. The power delivered by a numerical setting may vary greatly in different machines. Many units divide the power output in settings from 1 to 10. Position 5 in one unit may represent a different power output to position 5 in another unit. In addition, there will not always be equal differences between the unit settings, so there may be a different change in output between positions 1 and 2 than between positions 8 and 9. Modern units have overcome this hazard by indicating the power setting on a digital display.

Changes in electrosurgical unit

Prior to 1970, all electrosurgical units had a 'grounded design' which provided numerous potential alternative path-

ways for the discharge of diathermy current to ground, e.g. electrocardiogram leads. In 1970, isolated electrosurgery units were introduced. This meant that the ground electrode discharge returned to the electrosurgical unit. Thus, the whole circuit of electrosurgical current passed through the unit. Whilst this arrangement reduced the risk of inappropriate grounding routes, it did not solve the risk of burns from poor contact of the ground electrode with the patient. Poor contact leads to the development of high current density areas and a subsequent heating effect.

After 1980, some electrosurgical units employed a return electrode monitoring system, which detects failure of contact of the return electrode. Return electrode burns will be significantly reduced with this system.

Since 1990, the growth of minimal access surgery has increased the risk of inadvertent discharge from the active electrode through insulation failure or capacitive coupling. The Active Electrode Monitoring system now marketed by Encision provides an additional protective shield on the active electrode instrument, which picks up discharge of current from any point other than the active part of the electrode and inactivates the unit if such current is detected.

Electrosurgical equipment set-up

It is critically important to be certain that the diathermy ground plate is securely attached in the correct position. Whilst modern machines will give a warning signal when the plate is incorrectly attached, many machines will function if there is partial attachment. Partial attachment may lead to severe burns.

The positioning of the diathermy leads to and from the operating table needs care and attention. Capacitance current can develop alongside the diathermy lead delivering current to the active electrode anywhere along its length. Diathermy leads should not be secured with metal clips to the theatre gowns covering the patients.

Theatre staff must be trained in the use of electrosurgical equipment. Protocols should be in place regarding who attaches the equipment and who switches the machine on. If a patient's position is changed during the course of an operation, the electrosurgical unit should be switched off prior to the move, and the attachment of the ground electrode should be checked after repositioning.

Risk of fire/explosion

Flammable materials should not be used for skin preparation in gynaecological surgery. Theatre gowns can soak up such solutions which may also pool in the vagina or under the buttocks. Fires have been reported caused by sparks from diathermy current igniting flammable cleansing material.

Pacemakers

Monopolar diathermy should be avoided in patients with internal or external catheter pacemakers. There is a risk of inducing a rhythm disturbance, damage to the device or even electrical burns around the device. If monopolar diathermy is used, short bursts in the cutting mode are advisable. The pacemaker should not lie in the pathway of the diathermy current, but this will not guarantee safety as it is known that radiofrequency current can radiate away from a straight

pathway. The electrosurgical unit should be placed as far away from the pacemaker as possible because of the risk of 'noise' from the generator. When diathermy is required, a bipolar instrument should be used whenever possible.

Neuromodulators

Implanted neuromodulators are being increasingly employed for the treatment of lower urinary and lower gastrointestinal tract dysfunction. Monopolar or bipolar diathermy should not be employed when these devices have been implanted without consultation with the manufacturer. Similarly, deep brain stimulators may be implanted to treat patients with Parkinson's disease.

Keloid scarring

Keloid scarring has high tissue resistance so the diathermy ground electrode should not be placed over an area of keloid.

Joint prostheses

The joint prosthesis most commonly encountered by a gynaecologist is in the hip joint. If the prosthesis is unilateral, the diathermy ground plate should be sited on the opposite side. If bilateral prostheses are present, the ground plate should be placed on the flank. If a ground plate is sited over a prosthesis, current may be concentrated through the prosthesis in a preferential pathway and also in the tissue between the plate and the prosthesis, and a thermal injury may occur.

Lasers

A laser is a device capable of producing near-parallel beams of monochromatic light, either visible or invisible, at controlled intensities. This light can be focused, thus concentrating its energy, so that it can be utilized to treat various conditions. The term 'laser' is an acronym for 'Light Amplification by the Stimulated Emission of Radiation'. The process of stimulated emission was foreshadowed by Einstein at the turn of the century, but it was not until 1960 that the first optical device was constructed (Maiman 1960). Since that time, many lasers have been made but comparatively few have found their way into gynaecological practice.

Basic laser physics

A laser consists of three main elements: a power supply, an excitable medium and an optical resonator (Figure 4.4). Atoms or molecules within the medium are raised to high-energy states (Figure 4.5A) by the power supply, and, under normal circumstances, these would decay to the ground state by the emission of energy as photons (Figure 4.5B). By confining the process to an optical cavity and restricting the decay paths, stimulated emission (Figure 4.5C) can take place. This process produces a build-up of photons (light) at a particular wavelength inside the cavity. The laser output is a small fraction of this which is allowed to escape from one end of the cavity.

Many substances have been found to be suitable laser media — solids, liquids, gases or metallic vapours — but the

basic principles remain the same. A more detailed explanation of laser physics is provided elsewhere (Carruth and McKenzie 1986).

The radiation emitted is monochromatic (if only one decay path is involved), coherent and collimated. Collimation, or the near-parallel nature of laser light, can be exploited in many ways and is the main feature which makes such devices useful in the medical world. A single convex lens placed in the beam will bring it to a sharp focus, the size of which is dependent upon the width of the collimated beam. The use of different lenses or varying the lens-to-tissue distance alters the diameter of the beam at the point of contact with the tissue (Figure 4.6). This is referred to as changing the spot size.

The most important determinant of the effects of a laser upon tissue is the power density. This can be calculated approximately as:

$$PD = 100 \times W/D^2 \text{ [W/cm}^2\text{]}$$

where PD is power density, W is power output in watts and D is the effective diameter of the spot in millimetres. D can be measured by firing a short low-power pulse at a suitable target. The power density can be altered by changing either the power or the spot size, but the latter has the greater effect.

Light-tissue interaction

Light impinging on tissue is subject to the normal laws of physics. Some of the light is reflected and some is trans-

mitted through the air-tissue barrier and passes into the tissue where it is scattered or absorbed. Obviously the extent to which each process dominates is dependent upon the physical properties of the light and the tissue. The theory of light-tissue interaction is not as well developed as that of ionizing radiation (Wall et al 1988), but enough is known to explain the macroeffects upon which most laser treatments depend.

At very-low-energy density levels (power density \times time), say below 4 J/cm², a stimulating effect on cells has been observed, but above this level, the effect is reversed and suppression occurs (Mester et al 1968). As the energy density rises to 40 J/cm², indirect cell damage can take place if any sensitizing agents present become activated (e.g. haemato-porphyrin derivative). Direct tissue damage does not take place until approximately 400 J/cm², when the first thermal effects appear and photocoagulation occurs. Another 10-fold increase in energy density results in complete tissue destruction as it is sufficient to raise the cell temperature rapidly to 100°C, causing tissue vaporization. Obviously these are general observations and other properties of the incident beam will have an influence, but the general 10-fold relationship alluded to above holds although other parameters may be varied. Amongst the most important of these are

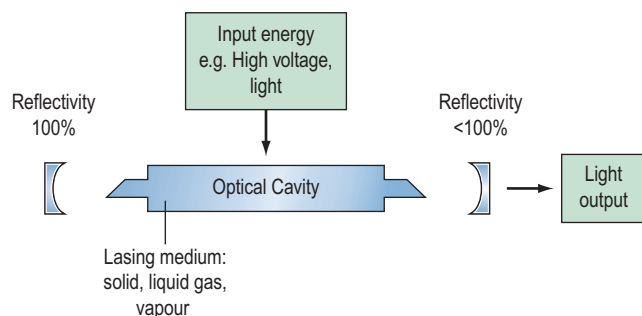

Figure 4.4 Typical laser systems.

Figure 4.6 Changing the focal length of the focusing lens while keeping the lens-to-tissue distance constant alters the spot size, the diameter of the beam at the point of contact with the tissue. (A) The focal length of the lens is greater than the lens-to-tissue distance. (B) The focal length of the lens is the same as the lens-to-tissue distance, i.e. the laser is focused on the tissue. (C) The focal length of the lens is less than the lens-to-tissue distance.

the wavelength and the pulsatile nature of the radiation involved.

The wavelength absorption characteristics of various body tissues are reasonably well understood, qualitatively if not quantitatively. Figure 4.7 shows the absorption curves for water, melanin and haemoglobin which, to a large extent, will determine the curves for tissue as a whole. In the ultra-violet and the middle-to-far infrared spectrum, absorption by water predominates whereas melanin and haemoglobin effects take over in the visible range. From this graph, it is easy to see that a particular laser, operating at a fixed wavelength, will be preferentially absorbed by one tissue constituent and its effects will be different from those of another laser with a different wavelength.

So far, it is implied that the laser is operated continuously for long enough for thermal effects to appear [continuous wave (CW) mode]. However, it is relatively simple, by means of a shutter or a controllable power supply, to switch the energy on and off rapidly (pulse mode). In general, the medical definition of a pulse is a burst of energy lasting 0.25 s or less. This does not correspond to the physics definition of a pulse, and care must be taken to avoid confusion. Methods of generating these pulses differ between lasers and the tissue effects can also vary. The reason for this phenomenon is shown in Figure 4.8.

Figure 4.8A shows the output from a CW laser which is modulated by a perfect shutter. The average power delivered to the tissue can be calculated from a knowledge of the CW power, the pulse repetition rate and width. In the case of an electronically controlled high-pulse power system where the time–power curve is not so closely defined (Figure 4.8B), it is much more difficult to determine the average power delivered. It is necessary to measure the energy of the pulse and the pulse repetition rate. The peak power, although impressive, is almost irrelevant.

The effects on tissue of this pulsatile radiation are to reduce the pure thermal effects (lower average power input) whilst

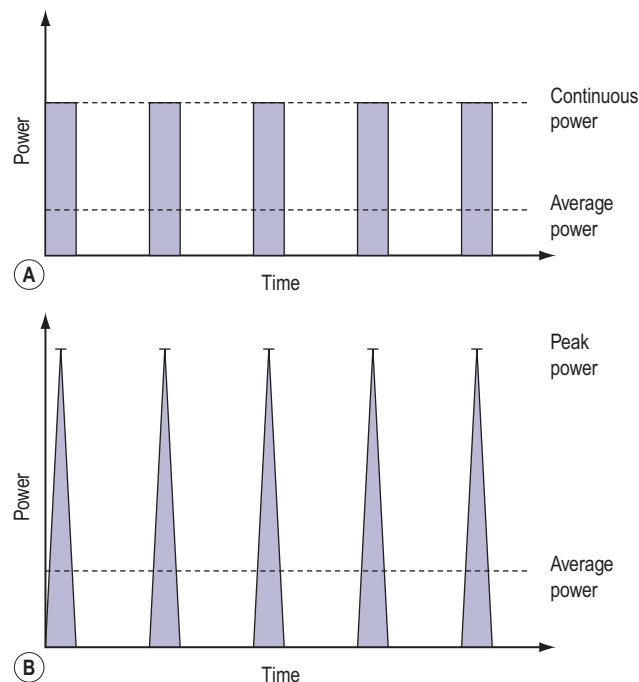

Figure 4.8 The effects of pulse irradiation.

maintaining and sometimes enhancing the vaporization potential. Provided the pulse repetition rate is sufficiently low to allow heat dissipation to take place between pulses, the tissue temperature will stabilize at a lower value. These effects are analogous to those induced by modulation in diathermy output which leads to the differences between cutting and coagulation diathermy referred to earlier.

Very short pulses, such as those produced by Q-switched lasers, can cause electromechanical breakdown in tissues because of the extremely high energy densities obtainable. In the early days, these lasers were tested in gynaecology but untoward side-effects were noted (Minton et al 1965).

Common laser systems

Two laser systems established themselves in gynaecological practice during the 1980s:

- the carbon dioxide (CO₂) laser; and
- the neodymium:yttrium aluminium garnet (Nd:YAG) laser.

These will be described in detail, with a further section devoted to other types of laser which are now entering general usage after extensive research.

Carbon dioxide laser

This is the system which has been most used in gynaecology since it was used for the first time in 1973 for the treatment of cervical erosions. This has been because of its clinical stability, ease of use, reliability and easy serviceability. It is a precise laser, especially in ultrapulse mode, making it useful for division of adhesions and accurate and safe vaporization of deposits of endometriosis (Sutton 1993). Although a major drawback is that its output cannot be transmitted by fibres, it has so far not been totally displaced by other lasers but is rivalled by modern diathermy equipment.

As the name implies, the active lasing medium is CO₂ gas. Efficiencies of 15% energy conversion to light output have been achieved. In fact, an analyser has used this ability to detect CO₂ in the breath! The first generation of CO₂ lasers used a flowing gas system with high-voltage direct current excitation. A gas mixture of CO₂, nitrogen and helium has been used to help achieve and maintain lasing conditions. Sealed tube lasers are now available with radiofrequency low-voltage discharges being used for excitation. This has made the machines smaller and removed the need for gas bottles.

The output radiation of 10.6 µm wavelength is well into the infrared region of the spectrum. This radiation is absorbed rapidly by tissue water, and therefore cuts and vaporizes more easily than it coagulates. Most of the incident radiation is absorbed within approximately 0.03 mm of the surface and intense heating occurs. Coagulation will only take place in small blood vessels less than 0.5 mm in diameter, but haemostasis can be facilitated by reducing the power density so that the zone of thermal damage around the central crater is wider.

As the 10.6 µm laser is invisible, an aiming beam must be used so that the operator can see where the therapeutic beam is going to have its effect. A helium–neon (HeNe) laser emitting at 628 nm (red) is incorporated into the system and optically aligned so that it coincides with the therapeutic beam. This alignment can degenerate and should be checked regularly.

As yet, there is no commercially available fibre which can transmit 10.6 µm light efficiently, so most commercial systems use some form of articulated arm. At each joint, there is a mirror which is adjusted so that the beam stays central despite movement between the two adjacent limbs of the arm. The choice of the mirror material is limited because of the need to reflect both the infrared CO₂ beam and the red HeNe aiming beam. It is possible to use waveguide delivery systems to avoid the use of mirrors, but this limits the manoeuvrability of the complete system.

The final delivery to the operation site can be carried out in two ways, both incorporating a focusing lens. For hand-held surgery, the lens at the end of a straight delivery tube focuses the beam on the operative field approximately 1 cm from the end of the tube. The lens-to-tissue distance can thus be varied at will so that the spot size will be changed within a narrow range (Figure 4.9A). Colposcopic delivery involves a mirror after the focusing lens which brings the beam into line with the viewing axis of the colposcope. This mirror is at the end of a joystick so that the beam may be moved around within the field of view (Figure 4.9B). Originally the spot size was changed using lenses of different focal lengths and so was limited to three or four predetermined sizes. Nowadays, the use of zoom optics allows infinite adjustment over a limited range (0.5–4 mm).

Power outputs of these lasers can be from a few watts up to 100 W continuous. Most commercial systems in gynaecology produce up to 25–35 W as this, coupled with a variable spot size, provides power densities of up to 6000 W/cm², sufficient for tissue cutting and vaporization at a controllable rate. The extra power provided by instruments producing 40–60 W is useful for dealing with patients who bleed during the procedure. Higher peak powers are available with modulation being employed to keep tissue temperatures within acceptable limits but with 'cleaner' cuts.

Neodymium:yttrium aluminium garnet laser

This device is a solid-state laser with the active neodymium ions being incorporated in an artificial crystal YAG. Pumping is achieved by energy input from a parallel gas discharge lamp, usually a water-cooled krypton tube, with the output radiation being refocused into the laser crystal. Output power levels up to 100 W continuous can be achieved, but, with a conversion efficiency of 1% or so, nearly 10 kW of input power is needed.

The energy produced is at a wavelength of 1.06 µm and is thus in the near-infrared. As such, it can be transmitted easily down a flexible fibreoptic delivery system and delivered to

Figure 4.9 Laser delivery systems. (A) Hand-held. (B) Colposcopically controlled.

many more anatomical sites than the CO₂ laser. The emergent radiation has lost its collimation and will diverge quite rapidly. Most fibres have a coaxial flow of gas, usually CO₂, to keep debris away from the end of the fibre. This is particularly necessary where contamination with blood or blood products may make continuous operation difficult.

As with the CO₂ laser, 1.06 µm Nd:YAG radiation is invisible. An HeNe laser (or other light source) needs to be incorporated into the device as an aiming beam. This is also a very useful safety feature as near-infrared radiation can cause irreparable damage to the retina. The Nd:YAG laser is easy to operate as a Q-switched laser. An optoelectronic switch is incorporated inside the laser cavity and the lasing action is prevented for a large percentage of the time. The photon energy therefore builds up to an even higher level than normal, and when the switch is eventually opened, a massive pulse of energy is delivered. The switch can then be closed and the process repeated. This type of action has found a use in ophthalmology where, by focusing the pulse to a very small spot, electromechanical breakdown of tissue can be induced with minimal surrounding damage.

The Nd:YAG laser has a greater depth of penetration and is more suited to hysteroscopic surgery (Sutton 1993). Hysteroscopic procedures include removal of fibroids and polyps, transsection of uterine septae, lysis of adhesions and endometrial ablation.

Other laser systems

Many other laser systems are used in medicine and the time period from research to common usage seems to be getting shorter. It is neither possible nor desirable to give a complete list, but some of the following examples have potential benefits for gynaecological surgery.

Metal vapour lasers

As their name implies, metal vapour lasers consist of a container filled with a heated and vaporized metal in an inert gas atmosphere at low pressure. The electrical discharge used must be pulsed because the necessary conditions cannot be sustained long enough for true CW operation to take place. Two types of metal vapour laser have found a use in medicine — copper and gold. The copper vapour laser produces two beams at 510 and 578 nm at up to 25 W power output. These by themselves are not particularly useful, although the green can be used as a substitute for the argon laser in dermatology. The output is ideally suited to act as an optical pumping source for a dye laser, which can be tuned to provide radiation for photodynamic therapy.

Photodynamic therapy

Photodynamic therapy is a treatment for certain tumours (Spikes and Jori 1987). It relies upon selective retention in tumour tissues of a drug (photosensitizer), such as haematoporphyrin derivative, which only becomes active on exposure to light of a particular wavelength. This provides highly selective tissue necrosis. Each photosensitizer has a particular spectrum of action requiring light of the appropriate wavelength for maximum absorption and effect. Clinically used sensitizers work between 420 nm (blue) and 780 nm (deep red). Longer wavelengths penetrate deeper (blue 1–2 mm and red >5 mm). As there are many decay pathways

available, the output is multi-wavelength, but a narrow wavelength range can be selected with suitable optical devices. The copper vapour and dye laser combination can produce over 5 W of red light at 630 nm, which is an absorption peak of haematoporphyrin derivative.

The other metal vapour device is the gold laser. The output of this is at 627.8 nm, a close match to the dye laser, without the added complication of two devices in series.

Argon laser

The argon laser, producing light at 488 nm (blue) and 514.5 nm (blue/green), is particularly favoured by ophthalmologists. The green output of the KTP laser (potassium titanyl-phosphate, 532 nm) has been more useful in gynaecology. The output is derived by taking the Nd:YAG beam and frequency doubling it in a KTP crystal, thus providing the surgeon with a choice of wavelengths (or even a mixture of the two). The advantages of the light lasers, argon and KTP lasers, over the CO₂ laser is their selective absorption by haemoglobin, less smoke plume production and an easy delivery system that uses lower power settings. They have been considered to be more suitable for treatment of ovarian endometriomas and ectopic pregnancies, as the CO₂ laser energy is strongly absorbed by the water molecule and is rendered ineffective in the presence of blood (Sutton 1993). The main disadvantage of the light lasers is the need to wear special protective glasses which can distort the view of the pelvis.

Ultraviolet lasers

Research into ultraviolet lasers has produced systems which seem to rely on non-thermal mechanisms for tissue destruction. These are the excimer lasers, a term derived from 'excited dimer', where the active medium is made from a combination of two substances which do not normally combine, such as a rare gas and a halide. These lasers have found a place in ophthalmology, and their potential for precise tissue removal offers the microsurgeon a very powerful tool.

The early use of lasers in gynaecology was in the treatment of cervical intraepithelial neoplasia, but subsequently spread to most other areas of the lower reproductive tract. The use of the laser in treatment of intraepithelial neoplasia of the genital tract is described in Chapter 38. Similar diathermy techniques are described in the same chapter.

We are under pressure to decrease health costs, so alternative, less-expensive technology has reduced the use of laser technology in recent years. However, lasers are still used in various clinical settings in obstetric and gynaecological surgery. Some examples include intrauterine laser ablation of placental vessels for the treatment of twin–twin transfusion syndrome (Robyr et al 2005), and ovarian drilling for ovulation induction in patients with anovulatory polycystic ovary syndrome (Farquhar et al 2007). Other uses are being investigated, but the evidence on safety and efficacy outcomes thus far is insufficient to support use in a non-research environment. Examples of these include laparoscopic laser myomectomy and percutaneous laser therapy for fetal tumours. There are also controversial areas regarding the use of lasers which have entered commercial gynaecology without much regulation or scientific evaluation, such as laser vaginal rejuvenation.

Laser safety

All laser systems in current use have no way of distinguishing between patient and operator. The desired effect on a patient can be a serious accident to the surgeon. The subject of the safe construction and operation of lasers in medicine and surgery is thus very important and must be understood by all involved. This section is biased in favour of UK regulations, but the situation is similar in most European countries and the USA, although, of course, regulatory bodies and documents will have different guises.

All lasers sold in the UK must conform to three basic standards. Electrical safety requirements are detailed in BS EN 60601-1-1 (British Standards Institution 2001) and non-ionizing radiation hazards are covered by BS EN 60825-1 and BS EN 60601-2-22 (British Standards Institution 1996, 2007). A further publication by the Medicines and Healthcare Products Regulatory Agency (2008) outlines good laser practice together with some additional equipment safety features. All these publications should be considered by a laser protection adviser (a health authority or trust appointee) who will assist each user in specifying and installing lasers in clinical surroundings. Although the requirements will vary from laser to laser and from site to site, the following sections outline the major considerations involved.

Nature of hazard

The body is divided into two regions for hazard analysis: the eye and the skin. In the visible region, which extends into the near-infrared, the eye is the organ at greatest risk. Outside this range, the eye is no different from the skin, except that corneal damage can lead to visual loss although the retina itself may be undamaged.

Radiation entering the eye is focused on the retina, and the power density can increase by up to 5×10^5 times so that a 50 W/m^2 corneal incident beam can become 25 mW/m^2 on the retina, with disastrous and irreparable results. Maximum permitted exposure levels are laid down by the regulations and are set well below known damage thresholds. Manufacturing and administrative controls are written to prevent operators, assistants and patients from accidentally receiving radiation in excess of these limits. There are separate values for the skin and the eye, with the latter being the more stringent.

Control of hazards

Lasers are currently classified into four groups from Class 1 to 4, with Class 1 being the least hazardous and Class 4 being the most hazardous. Class 3 is also subdivided into two classes, 3A and 3B. It is the manufacturers' responsibility to classify a laser, but, once this is done, it will rarely be changed. Stringent safety precautions must be introduced when Class 3 and 4 lasers are in use. Most medical lasers are Class 3B or 4 and do need such safeguards. Aiming beams are usually Class 1 or 2 and present a minimal hazard.

In addition to classifying the laser, manufacturers must ensure that the equipment complies with the specification for its particular class. Generally all systems will have a key control and some way of monitoring the power being delivered to the patient. It should also indicate, either visually or

audibly, when the laser shutter is opened and the maximum permitted exposure is exceeded.

Administrative controls are framed to ensure that the equipment is then used safely. A set of local rules must be drawn up which specify who is allowed to use a laser and where it can be used. A laser controlled area must be defined and the activities within that area must be controlled. There must be no possibility of radiation in excess of the maximum permitted exposure level passing out of the area, even if this means blocking windows and doors. Warning signs must be exhibited at the entrance to the laser controlled area, and door interlocks can be used but are not obligatory. Examples of such local rules can be found in other texts (Stamp 1983, Medicines and Healthcare Products Regulatory Agency 2008).

All personnel within the laser controlled area must either be protected from the radiation by the inherent optical properties of the operating equipment or must wear appropriate spectacles. For example, any common translucent glass is impervious to CO_2 laser radiation. Precautions for the Nd:YAG laser are more complicated, and special eyewear for observers and filters to protect the operator from back-reflection through a delivery system are required. Obviously such devices cannot be used when the aiming beam is derived from the therapeutic beam. In this case, an additional safety shutter is required to protect the surgeon during treatment. Precautions against eye damage must be rigorously implemented for all present, including the patient.

Fire is an ever-present hazard with the use of Class 4 lasers and simple precautions must be observed. Aqueous instead of spirit-based solutions should be used and paper drapes should be avoided. CO_2 radiation is readily absorbed by water, and by keeping swabs soaked in water or saline, tissues adjacent to the operation site can be protected. A suitable fire extinguisher should always be available. Greater care must be exercised in the presence of inflammable anaesthetic gases. Endotracheal tubes have been ignited by a laser with serious results (Bandle and Holyoak 1987). While this situation is not likely to be encountered in gynaecology, inflammable gases may be passed rectally by the patient during laser treatment of the lower genital tract, posing a theoretical risk of explosion.

A by-product of laser treatment (and diathermy to a certain extent) is a plume of smoke and debris, with a characteristic odour. This must be evacuated and collected from as near as possible to the impact zone for two important reasons. First, the emission of smoke is likely to obscure the operating site. This is particularly true in cervical or vaginal surgery. Second, doubts have been raised over the viability of particles contained within the plume (Garden et al 1988). Although the evidence is not overwhelming, it is essential that the smoke should be adequately extracted and filtered.

Unintentional reflections of the laser beam striking an instrument can be dangerous. Although it is very unlikely that radiation reflected in this way will be sufficiently focused to cause damage, it is sensible to ensure that the instruments are not highly polished and scatter any incident radiation. It should not be assumed that the reflecting qualities of a surface are the same at visible and far-infrared wavelengths, so care should be exercised in the choice of speculae and other operating instruments.

Conclusions

Diathermy techniques have improved markedly and have replaced laser techniques developed in the 1970s and 1980s

on economic grounds. However, there is still a place for the use of lasers in gynaecology, particularly as new devices are made available and as yet unknown light–tissue interactions are discovered and exploited. Interactions between light, tissue and drugs hold much promise.

KEY POINTS

1. Monopolar diathermy uses electric currents to cut or coagulate. Bipolar diathermy can only be used for coagulation; however, bipolar cutting devices are in development.
2. Great care must be taken to prevent accidental burns during diathermy use. Current can flow to organs not in direct contact with the active electrode.
3. Insulation failure, direct coupling and capacitive coupling are the three major safety issues in the use of diathermy.
4. Lasers produce near-parallel beams of monochromatic light.
5. The beam can be focused by a lens to alter the diameter of the beam at the point of contact with the tissue (the spot size).
6. The power density is the most important determinant of the effects of the laser upon tissue.
7. The greater the power density, the less the thermal effect and the less the haemostatic property of the beam.
8. The beam of a CO₂ or an Nd:YAG laser is invisible so a guiding HeNe laser is required.
9. The eye must be protected from accidental exposure to laser energy. This is especially important with Nd:YAG endoscopic systems.

INTRODUCTION	59	SAFETY ISSUES	76
METHODOLOGY	59	CONCLUSIONS	77
CLINICAL APPLICATIONS	62	KEY POINTS	77

Introduction

Since the discovery of X-rays by Roentgen in 1895, there has been an explosion in technology for imaging the human body; in addition to ionizing radiation, high-frequency sound (Wade 1999), radiolabelled pharmaceuticals and non-ionizing radiation in strong magnetic fields are used. The parallel expansion in computer technology has enabled the development of cross-sectional imaging using computed tomographic (CT) techniques, and three-dimensional imaging using magnetic resonance imaging (MRI) data.

Methodology

X-ray techniques

Standard radiographs are obtained by placing the patient between an X-ray source and a photographic film. Images are produced by the attenuation of X-ray photons by the patient. As a result, structures of interest are often obscured by the attenuation of photons by other overlying structures. A basic limitation of the standard X-ray technique is the effect of scattered photons adding to the image noise and degrading the quality of the final image. Various manoeuvres have been adopted to reduce this effect, such as scatter grids. The linear tomograph is obtained by the synchronous movement of the X-ray tube and the film, causing a blurring of the overlying and underlying structures while leaving the plane of interest in focus. This procedure increases the detection of lesions such as chest metastases.

Contrast studies

To increase contrast in the soft tissues, an iodine-containing agent may be injected into the lumen of a cavity such as the uterus and fallopian tubes (hysterosalpingogram) or blood vessels (angiogram). Such contrast agents are widely available in ionic and (more expensive) non-ionic forms. The less toxic non-ionic preparations are preferred.

Ultrasound

In Glasgow in 1950, Ian Donald used an industrial flaw detector, designed for testing the integrity of steel boilers, to demonstrate that the massive abdominal swelling of one of his patients was fluid and not solid (Kurjak 2000). A large ovarian cyst that proved to be benign was subsequently removed. Since then, the rapid and continuing evolution of ultrasound technology has led to a proliferation of applications in almost all aspects of medicine and surgery.

Ultrasound waves are generated by a piezoelectric crystal mounted in a transducer housing, and the whole construction is referred to as a 'probe'. Piezo materials respond to an applied voltage by changing thickness, and produce electrical signals of a few millivolts when compressed. In the final image, the resolution along the beam is determined by the wavelength, while the resolution across it depends on the width of the beam, which is improved by focusing using combinations of lenses and electronic mechanisms.

The time from transmission of the ultrasound pulse to receipt of an echo is translated into depth using the speed of sound in tissue. Echoes arise wherever the pulse of ultrasound encounters an interface between tissues of different acoustic impedance, which may simplistically be regarded as changes in density. Thus, homogeneous materials such as clear fluids are echo-free, while low-level echoes are given by the interfaces between the various components of soft tissue structures. Stronger echoes result from the interface between fibrous tissues (high impedance) and fatty tissues (low impedance), and maximal echoes are given by interfaces between soft tissues and bone or gas, both of which are effectively opaque to ultrasound. To form a real-time image, the beam is electronically swept through a region of tissue and the images are pie-shaped (sector and curved arrays) or rectangular (linear probes).

The choice of frequency is a compromise between the spatial resolution and the depth of penetration required. The higher the frequency, the better the resolution, but the

greater the attenuation of the beam within the tissues. Hence, for abdominal scanning, frequencies of between 3.5 and 5 MHz are commonly employed. Probes designed for intracavitary and intraoperative use employ higher frequencies (8–15 MHz) because the organs of interest are closer to the transducer. This enables higher resolution images to be obtained, and also allows study of the movement of structures when pressure is applied to the probe, which gives important diagnostic clues on their relative mobility. The drawbacks of transvaginal scanning are practical (intolerance of the probe by the very young and old, and in the presence of scarring) and diagnostic (the depth of view is limited to approximately 70 mm) (Bennett and Richards 2000). By sweeping an array through the tissues, a three-dimensional scan can be created; while most useful in obstetrics to visualize complex structures such as the fetal face, it also displays uterine anatomy well (Alcazar and Galvan 2009).

The interactivity of ultrasound is an important feature; it is effectively an extension of clinical examination. Ultrasound also provides numerous views during the real-time examination and facilitates guided needle biopsies. However, it has many limitations, notably the variable image quality, that frustrate its application. An important problem is the complete barrier posed by bowel gas, which is why a full bladder is required for transabdominal scanning.

Doppler operates by detecting the change in frequency of ultrasound echoes caused by movement of the target. In the simplest system, this is done continuously with only minimal control of the beam direction. Continuous wave Doppler is well suited to fetal heart monitoring, especially because movements of the fetus do not interrupt the signal. In gynaecology, the vessels of interest are small so precise placement of the Doppler sample is a prerequisite. This can be achieved with pulsed Doppler. The Doppler gate is superimposed on a real-time image that allows the target to be pinpointed (Figure 5.1). The Doppler signal depicts a range of blood velocities occurring in the selected vessel over time. Output can be audio or as a strip chart on which intensity indicates the strength of the signal at each velocity in the spectrum. A variety of measurements can be made from these tracings, the most useful of which are systolic/diastolic velocity ratios. These are measures of the arteriolar resistance to flow, with a low value indicating low vasomotor tone, typical of the placenta and the corpus luteum. This pattern also occurs in inflammation and malignancy. High indices are typical of inactive tissue, such as the resting uterus. Doppler can be used to measure fetal and uteroplacental blood flow, thereby producing physiological information (Brinkman and Wladimiroff 2000).

In colour Doppler scanning, the same process is applied across an area of interest. The velocity signals are presented as a colour-coded overlay, superimposed on the real-time scan (Figure 5.2). Although the Doppler information is less rich than with spectral Doppler (only the mean velocity or the amount of flow is depicted), the angiogram-like map provides information on the morphological arrangement of the vascular tree, and its sensitivity allows vessels as small as approximately 1 mm in diameter to be detected. Colour Doppler is often used to locate a vessel to guide placement of the spectral Doppler gate for haemodynamic analysis.

Figure 5.1 Spectral Doppler. In this scan of an ovarian cancer, the Doppler gate (arrow) has been positioned on the tumour. The spectral tracing is in the lower portion of the figure and shows the typical low-resistance pattern of malignant neovascularization with marked diastolic flow.

Figure 5.2 Colour Doppler of an ovarian carcinoma. On colour Doppler, flow signals are colour coded and presented as an overlay on the grey-scale image in the left-hand panel of this transvaginal scan, while the right-hand panel shows the grey-scale image on its own. The neovascularization in this ovarian carcinoma is shown as knots of colour. Apart from providing a graphic display of vascularity, a useful feature of colour Doppler is to guide placement of the gate for spectral Doppler tracings.

A recent advance has been the introduction of contrast agents for ultrasound in the form of microbubbles for injection. Not only does the signal improvement they produce allow smaller vessels to be detected, but they can be visualized in grey scale to reveal regions of flow in real time. In addition, they can be used as tracers by tracking a bolus as it crosses a tissue of interest, and this may yield valuable functional information.

Computed tomography

The sensitivity of conventional radiography may be improved by using a radiation detector such as a scintillation crystal and a photomultiplier tube. By measuring the attenuation of a finely collimated beam of radiation, passing through the patient at multiple angles, it has been possible to produce images of very high quality. A computer uses the attenuation

of each beam passing through the patient to calculate the attenuation coefficient for each area of tissue in the cross-section of interest. The final images are reconstructed using a filtered back-projection technique and displayed in grey scale as a series of attenuation units (with values between +500 and -500) in a matrix of 512×512 or 1024×1024 elements. The reconstruction of data is limited to the transverse (transaxial) plane. This imaging technique revolutionized modern medicine in the 1970s, but its impact on gynaecology has been less marked.

Magnetic resonance imaging

MRI depends upon the magnetic properties of certain atomic nuclei which, when placed within a magnetic field and stimulated by radio waves of a specific frequency, will absorb and then re-emit some of this energy as a radio signal. This phenomenon of nuclear magnetic resonance (NMR) was first described by Felix Bloch and Edward Purcell in 1946. NMR as a basis for an imaging technique was proposed some 30 years later by Lauterbur.

Nuclei possessing magnetic properties have an odd number of protons or neutrons. The charged particles are spinning, which causes them to behave as tiny bar magnets. If placed within a magnetic field, a majority of protons will line up in the direction of the magnetic field. In addition, their axes are tilted and caused to rotate like small gyroscopes. The frequency of this precessional movement is directly proportional to the strength of the applied field and is called the 'Larmor frequency'. The hydrogen proton gives a relatively high signal due to its abundance in biological tissues. Other potential NMR isotopes include ^{13}C , ^{23}Na , ^{19}F and ^{31}P .

If a pulse of radio waves is imposed on the nuclei, a strong interaction or 'resonance' will occur when the frequency coincides with the precessional frequency of the nuclei. The energy absorbed by the nuclei is then re-emitted as a signal that can be detected in a receiver coil situated around the sample. The initial strength of this signal is proportional to the proton density of the sample. It will then decay in an exponential fashion as the disturbed protons relax back to their original state. The T_1 relaxation time is described as the time taken for the stimulated protons to return to their initial state. The T_2 relaxation time is that taken for the precessing nuclei to get out of step with one another. A variety of sequences of radio wave pulses have been devised so that the resulting signal is weighted to different degrees by the proton density and the T_1 and T_2 relaxation times.

The contrast between different tissues in MRI can be manipulated by altering the pattern of radio waves applied. This is done by changing the time constants associated with the different sequences of radio waves: the repetition time, echo time or inversion time. A further advantage of MRI is the ability to obtain images in multiple planes, such as sagittal, coronal or oblique planes, without moving the patient.

The female pelvis is suitable for MRI examination because of the minimal effect of respiratory motion on the pelvic organs. By placing the receiver coil adjacent to the tissue of interest (e.g. endovaginally to maximize signal from the cervix), very-high-resolution images of an area of interest

may be obtained. However, as the data to produce a set of images are accumulated over 5–10 min, patients are required to remain still during this time. If multiple sequences and multiple planes are employed, the total imaging time may exceed 30 min which reduces patient tolerance. However, newer faster pulse sequences with breath-hold techniques and improved computer software are greatly reducing scan times. Recently, open design MR scanners and production of MR-compatible equipment has produced an explosion in the field of 'interventional MRI'. This has expanded the applications of MRI from being purely diagnostic to its use during treatment, such as for placing brachytherapy implants (Popowski et al 2000) or monitoring thermal ablative therapy.

Radionuclide imaging

Unlike the other imaging modalities, radionuclide imaging provides physiological rather than anatomical detail. Modern gamma cameras are capable of accurately imaging the distribution of administered radiopharmaceuticals, and the use of tomographic systems for single photon emission tomography has improved image resolution. In gynaecological oncology, radiolabelled monoclonal antibodies may be employed in the localization of malignancies (radioimmunoscintigraphy) and in their treatment (radioimmunotherapy).

The purity and specificity of monoclonal antibodies gives them an important role in tumour detection and possibly in the targeting of antitumour agents. Different anticytokeratin antibodies may help in distinguishing a primary ovarian adenocarcinoma from a metastatic adenocarcinoma, especially of colorectal origin (McCluggage 2000). These antibodies have also helped to clarify the origin of the peritoneal disease in most cases of pseudomyxoma peritonei. In recent years, several studies have also investigated the value of a variety of monoclonal antibodies in the diagnosis of ovarian sex cord stromal tumours, and in the distinction between these neoplasms and their histological mimics. Of these, anti-alpha-inhibin and CD99 appear to be of most diagnostic value (Choi et al 2000). Antibodies should always be used as part of a larger panel and not in isolation.

The antibodies or antibody fragments are radiolabelled with a gamma-emitting radionuclide such as $^{99\text{m}}\text{Tc}$, ^{131}I , ^{123}I or ^{111}In . A subcutaneous test dose is no longer given because of the immune response it may generate in the patient. If ^{131}I or ^{123}I is employed, oral potassium iodide is given to block thyroid uptake of free radioactive iodide. In addition, blood pool subtraction techniques are required for ^{131}I studies to simulate the non-tumour distribution of labelled antibody. This is not necessary for ^{123}I - or ^{111}In -labelled preparations.

Following injection of the antibody, a gamma camera provides serial images of the distribution and uptake of radiolabelled antibody between 18 and 72 h after the antibody has been administered. The radionuclide ^{111}In is ideally suited for tomographic studies using images produced by a gamma camera mounted on a gantry which rotates through 360° . The images are reconstructed by computer in the same manner as X-ray CT. ^{111}In -labelled antibody is taken up into the liver, spleen, bone marrow and, occasionally, adrenal

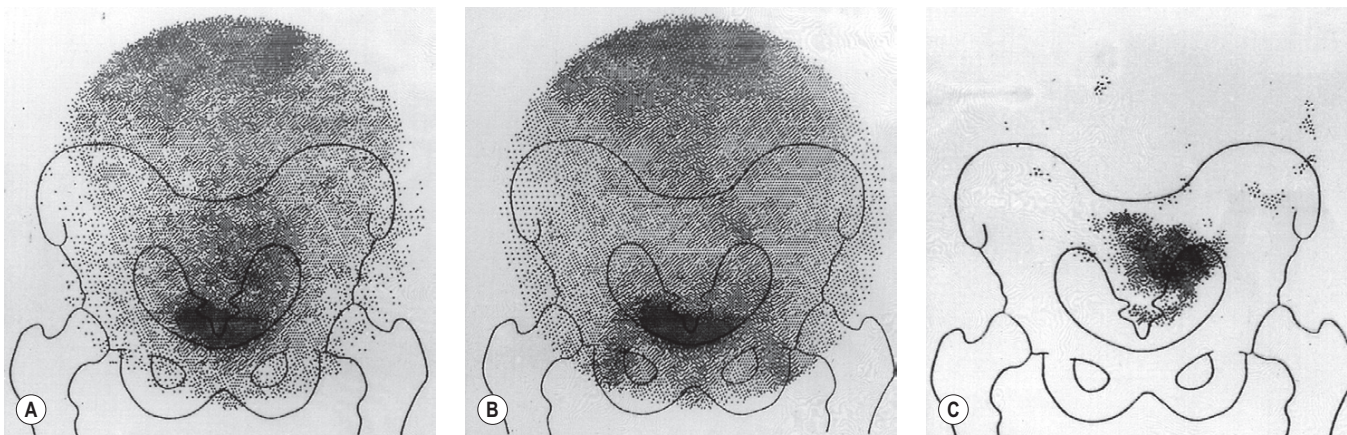

Figure 5.3 Radionuclide scan: primary ovarian carcinoma. Anterior view of the pelvis with 80 MBq ^{111}In -labelled OC-125.

glands but is a more suitable radiolabel than ^{131}I . Excretion of ^{111}In into the bladder has not been a problem, although non-specific bowel uptake may account for false-positive results. An example of an ^{111}In study is shown in Figure 5.3. A central area of increased uptake is apparent at the site of a primary ovarian cancer.

^{18}F FDG (^{18}F fluorodeoxyglucose) is a non-specific positron-emitting tracer. It is an analogue of glucose, thereby reflecting metabolism and detecting the increased glycolysis associated with several tumour types. It gains entry into cells by membrane transporter proteins, such as Glut-1, which are expressed in many tumours. It is phosphorylated intracellularly to FDG-6-phosphate and retained within malignant cells. Tumour hypoxia may also increase ^{18}F FDG accumulation via activation of glycolysis. The quantitative parameter used is typically a standardized uptake value (SUV), which represents the tissue activity within a region of interest corrected for the injected activity and the patient's body weight. A new lesion (Figure 5.4) or a rise in SUV within a lesion indicates disease progression. Whether this can be used as a marker for early therapy remains to be proven.

Angiography

Diagnostic and therapeutic angiography have made great strides in recent years with the development of catheters whose tips can be manipulated. This allows considerable control over the guidance of these catheters into selected vessels. In parallel with this, ingenious devices have been devised which can be introduced via these catheters for purposes as diverse as angioplasty and embolization.

In gynaecological practice, the main use of angiography is the control of pelvic bleeding, but both the diagnosis of pelvic venous thrombosis and the prevention of subsequent pulmonary embolism are important roles for this exciting new technique. Pelvic arteriovenous malformations are most readily diagnosed and treated with angiography, and pelvic varices causing chronic pain may be managed in the same way. Selective sampling of gonadal venous blood and steroid hormone assay can be valuable in the preoperative assessment of phenotypic women with chromosomal abnormalities and intra-abdominal gonads of uncertain nature.

Clinical Applications

Normal anatomy and variations

Uterus

The normal uterine cavity is delineated as a triangular structure on hysterosalpingography, with the cornua and the internal cervical os as the corners. Intracavitary abnormalities, both congenital and acquired, such as internal septations and divisions may be defined using this technique (Figure 5.5). Similar information can be acquired with ultrasound following instillation of saline into the uterine cavity (hysterosonography) (van den Brule et al 1998).

Figure 5.5 Hysterosalpingogram: contrast outlining the cavities of a bicornuate uterus. Free spill into the peritoneal cavity can be seen on the right (arrow).

On ultrasound, the uterine cavity is normally represented by a bright line of apposition of the endometrial layers, although occasionally a trace of fluid can be seen at menstruation. Persistent fluid or fluid in a non-menstruating woman is abnormal. In adolescence, it may be caused by vaginal atresia, where the upper vagina dilates more than the uterus so that haematocolpos dominates the picture, while in postmenopausal women, cervical stenosis, either fibrotic or malignant, must be considered. Ultrasound is also useful in detecting the position of an intrauterine device; provided the coil lies in the uterus, it is easy to locate, but a coil that has penetrated through the myometrium is obscured by echoes from bowel gas (Figure 5.6).

The entire uterus can be imaged using ultrasound (Figure 5.7) and its size measured accurately. This is useful in precocious or delayed puberty and in planning brachytherapy. The endometrium is seen as an echogenic layer of uniform texture, often with a fine echo-poor margin. Its thickness varies through the menstrual cycle from 12 mm premenstrually (double-layer thickness) to a thin line after menstruation. The endometrium gradually thins after menopause unless supported by hormones.

The morphology of the normal uterus, however, is best defined on MRI where its zonal architecture may be recognized (Hricak et al 1983). On T_2 -weighted images, the endometrium is seen as a central high-signal stripe which increases in thickness in the secretory phase of the menstrual cycle. The inner myometrium (junctional zone) is of lower signal intensity than the outer myometrium on T_2 weighting, and correlates histologically with a layer of more densely packed smooth muscle.

Fallopian tubes

The patency of the fallopian tubes may be demonstrated on hysterosalpingography where filling and free spill into the peritoneal cavity may be seen (Figure 5.5). Ultrasound contrast salpingography is currently being evaluated to reduce

Figure 5.6 Two views of an intrauterine device in the uterine cavity (arrows) with a coexisting pregnancy (arrowheads).

Figure 5.7 Transvaginal scan of the uterus. In this scan, taken in the luteal phase of the cycle, the secretory endometrium is seen as an echogenic band in comparison with the relatively echo-poor myometrium.

the radiation dose to the ovaries in patients trying to conceive. Normal uterine tubes cannot be demonstrated on ultrasound, but instillation of microbubble contrast agents into the uterus and tubes permits their visualization and can be used as an initial screening test for tubal patency. Although

the anatomical detail is less than that offered by conventional X-ray salpingography and false-positive results occur, this technique of ultrasound salpingography seems likely to find an important role as an initial screen; if the tubes are demonstrated to be patent, no further investigation is necessary and this should result in a reduction of radiation exposure (Van Voorhis 2008).

The normal fallopian tubes are too small in calibre and of too variable a course to be reliably imaged using a cross-sectional technique such as CT or MRI.

Ovaries

The ovaries are best imaged with ultrasound (either transabdominal or, preferably, transvaginal). Changes in their appearance can be correlated with their functional status. Infantile ovaries are small (except in the neonate when hypertrophy and follicles stimulated by maternal hormones may be a surprising finding) and they enlarge before puberty. Follicular development begins before menstruation, but these cycles and those at the menopause are often imperfect

so that follicles may persist and continue enlarging for several months. Normally, ovulation occurs at a follicle size of 20–25 mm diameter and the echo-free follicle is replaced by a corpus luteum which can be cystic or solid. Corpora lutea produce a confusing variety of appearances, whose only consistent feature is their transience (Figure 5.8A–C). In doubtful cases, a rescan at 6 weeks to image them at a different phase of the cycle may be needed to resolve their identity. The postmenopausal ovary is usually too small to identify with ultrasound.

On CT and MRI, the normal ovaries are often difficult to define, but may be recognized on short inversion recovery MRI sequences as very-high-signal foci in the adnexae.

Ovarian varices

The pelvic congestion syndrome is one of many causes of chronic pelvic pain, and is associated with the presence of large varices within the broad ligaments (Liddle and Davies 2007). When pelvic symptoms are severe, there may be gross dilatation of the ovarian veins, with reflux down into the

Figure 5.8 Transvaginal scans of the ovary. (A) An inactive ovary is indicated by the caliper marks. It is surrounded by a small amount of free fluid and contains minute developing follicles. (B) Two views of an ovary containing a 3-cm simple cystic structure which presumably represents an unruptured follicle. (C) An ovary in the luteal phase containing a solid corpus luteum.

pelvis and often into the legs. These vessels are best demonstrated by selective ovarian venography, although they may also be imaged with Doppler ultrasound (Haag and Manhes 1999). Venography is performed via a femoral or internal jugular venous approach, and the ovarian veins are selectively catheterized with an appropriately shaped angiographic catheter. Satisfactory retrograde opacification of pelvic varices is achieved by injecting contrast medium through the selectively placed catheter with the patient almost upright on a tilting table, while the Valsalva manoeuvre is performed.

Treatment of this condition is primarily surgical and consists of venous ligation. Symptomatic relief has been reported following transcatheter ovarian vein embolization (Ganeshan et al 2007).

Investigation of female infertility

The success of in-vitro fertilization (IVF) has been due, in part, to the correct timing of ovulation and subsequent oocyte recovery that ultrasound can provide. Using transabdominal scanning, ovarian follicles of 3–5 mm diameter can be visualized. They appear as echo-free structures amidst the more echogenic ovarian tissue. Their rate of growth is linear and the mean diameter prior to ovulation is 20 mm (range 18–24 mm). Structures within the follicle, such as the cumulus oophorus, can also be visualized. Following ovulation, internal echoes appear because of bleeding. Free fluid may also be observed in the pouch of Douglas.

Transvaginal sonography has largely replaced the transabdominal approach in infertility practice because of the superior anatomical display and because it allows precisely guided aspiration of follicles and fluid in the pouch of Douglas. More precise measurement of follicles is possible, and the corpus luteum is easily recognized. In the midluteal phase, it appears as an oval structure 30–35 mm long and 20–25 mm wide with a wide variety of sonographic appearances (Baerwald et al 2005). Endometrial reflectivity patterns have been proposed as another way to assess ovulation (Randall et al 1989). Ultrasound can only provide presumptive evidence of ovulation/pregnancy. The collection of secondary oocytes constitutes definitive evidence of ovulation. The appearance of internal echoes before the follicle reaches 18 mm or continuous enlargement to 30–40 mm indicates follicular failure.

Ultrasound is also useful for accurate timing of artificial insemination, while a postcoital test can help to differentiate between inadequate sperm penetration and poor mucus production in the presence of immature follicles. Ultrasound scanning is also employed to monitor patients on clomiphene therapy, and there is good correlation between follicular diameter and plasma oestradiol concentration. Ovarian hyperstimulation syndrome is uncommon if gonadotrophin therapy is monitored by ultrasound in conjunction with measurements of plasma oestradiol levels.

The waveforms of blood flow in vessels supplying the ovaries of women undergoing IVF have been studied using transvaginal power Doppler ultrasound (Palomba et al 2008). The observation of blood flow patterns did not improve any reproductive outcomes and is currently not advocated in IVF programmes.

MRI is valuable in the investigation of infertility where uterine pathology is suspected, and provides a particularly high diagnostic yield in patients with dysmenorrhoea and menorrhagia (deSouza et al 1995). It should be part of the investigation of patients with persistent unexplained infertility awaiting costly procedures such as gamete intrafallopian transfer and IVF. MRI should also be used before myomectomy in order to differentiate between leiomyoma and adenomyoma, as attempts to perform a myomectomy on a localized adenomyoma often result in extensive uterine damage.

Adenomyosis and endometriosis

The diagnosis of adenomyosis is often suggested by symptoms of hypermenorrhoea and dysmenorrhoea, but similar symptoms are also produced by leiomyomas. Hysterosalpingography may show multiple small tracks of contrast extending into the myometrium but is now obsolete. Ultrasound in skilled hands may be useful (Dueholm and Lundorf 2007).

Adenomyosis is best demonstrated on T₂-weighted MRI, with which two patterns (focal and diffuse) can be recognized (Hricak et al 1992, Byun et al 1999). In focal adenomyosis, there is a localized ill-defined mixed-signal-intensity mass (adenomyoma) within the myometrium (Figure 5.9). Diffuse adenomyosis presents with diffuse or irregular thickening of the junctional zone, often with underlying high-signal foci (Figure 5.10). Pathologically, this represents smooth muscle hypertrophy and hyperplasia surrounding a focus of basal endometrium. It is the smooth muscle changes that are easily recognized by MRI rather than the foci of heterotopic glandular epithelium. Values for junctional zone thickness from >5 to >12 mm have been suggested for the diagnosis of adenomyosis. In the authors'

Figure 5.9 Focal adenomyoma. T₂-weighted spin-echo (SE 2500/80) midline sagittal section through the uterus, demonstrating a large ill-defined mixed-signal intensity mass characteristic of an adenomyoma (arrows).

Figure 5.10 Diffuse adenomyosis. T₂-weighted spin-echo (SE 2500/80) midline sagittal section through the uterus, showing thickening and irregularity of the low-signal band of the junctional zone (short arrows). Diffuse infiltration of a mixed-signal lesion (long arrow) is seen in the posterior wall.

Figure 5.11 Endometriotic deposits. T₂-weighted spin-echo (SE 2500/80) midline sagittal image; fluid levels are seen in cystic lesions with mixed-signal intensity suggestive of haemorrhage (arrows).

experience, however, the thickening of the junctional zone that is described in adenomyosis (Reinhold et al 1999) is not diagnostic of adenomyosis on its own; it may be seen in hypermenorrhoea where no pathological evidence for adenomyosis has subsequently been shown. In these instances, absolute values for junctional zone widths are unhelpful (Hauth et al 2007), and ratios to the width of the outer myometrium or the cervical stroma may be more meaningful.

The lesions of endometriosis are difficult to detect with imaging techniques, mainly because of their small size. Only larger endometriomas can be detected on ultrasound and are seen as well-defined spaces, most commonly in the adnexal region (Figure 5.11). The role of MRI in the diagnosis of endometriosis also depends on the site of the endometriotic implants; deposits on the ovarian cortex are much more readily identified than small peritoneal deposits. The latter are recognized at laparoscopy but may be missed on MRI (Brosens et al 2004). Endoscopic ultrasound has been advocated to improve the diagnosis of endometriotic infiltration into the digestive tract (Dumontier et al 2000). MRI is particularly valuable in detecting deep enclosed endometriosis typically found in the uterosacral ligaments and rectovaginal septum (Figure 5.12) commonly associated with pelvic pain. Deep pelvic endometriosis consists mainly of fibromuscular rather than endometrial tissue (Del Frate et al 2006), and often goes undetected on visual inspection of the pelvic cavity because of its position. However, MRI lacks sensitivity in detecting rectal endometriosis if the rectum is not distended (Kinkel et al 1999). More recently, there have been isolated reports correlating an increased junctional zone thickness with endometriosis in patients with infertility (Kunz et al 2000).

Figure 5.12 Rectovaginal endometriosis. T₂-weighted spin-echo (SE 2500/80) sagittal section demonstrating a rectovaginal mass (arrows) in a patient with laparoscopically proven endometriosis. This was not detected at laparoscopy because it is retroperitoneal.

Leiomyomas

The most common cause of disturbance of the normal uniform echo texture of the myometrium is fibroids. Generally, a focal thickening occurs and their position in the uterus can be determined. Submucosal fibroids, or the

polyps they may produce, can be mistaken for endometrial thickening, although occasionally the way they move with normal uterine contractions is diagnostic. Instillation of saline into the uterine cavity, a form of ultrasound contrast, provides much more information about intracavitary lesions. Pedunculated or broad ligament fibroids frequently masquerade as extrauterine masses. The echo texture of fibroids is very variable, in accordance with their histological spectrum. A characteristic is calcification which is easily recognized on ultrasound as intensely reflective foci with accompanying acoustic shadowing.

MRI has been reported to be superior to ultrasound for the diagnosis of leiomyomas (Ascher et al 1994). Characteristic well-defined low-intensity masses are seen within the myometrium on T₂-weighted scans, often with high-signal foci within them. There are no completely reliable features that distinguish fibroids from leiomyosarcomas on ultrasound or MRI, and even Doppler has proved disappointing here. In those patients presenting with more advanced disease, alterations in the lesion margins may suggest malignant change.

Ectopic pregnancy

Traditionally, ultrasound has been used to exclude an ectopic pregnancy by demonstrating an intrauterine pregnancy, but this sign is unreliable in assisted pregnancy because the likelihood of coexistent intra- and extrauterine pregnancies is not negligible. The positive diagnosis of ectopic pregnancy requires the demonstration of an extrauterine fetal heart. Secondary features that may be recognized are an adnexal mass with peritrophoblastic Doppler signals, free fluid in the pelvis and increased endometrial thickness. With a combination of these features, the negative predictive value of an ultrasound examination may be 96%. However, significant problems can arise in distinguishing an ectopic pregnancy with a pseudogestational sac from an early normal or failed intrauterine pregnancy.

The role of ultrasound in the diagnosis of ectopic gestations has been strengthened by the use of transvaginal probes and the introduction of Doppler. A weakness of transabdominal scanning was the difficulty in demonstrating the sac itself, because of gas in overlying or adherent bowel. With transvaginal scanning, the adnexal sac can be demonstrated and women at high risk can be monitored through the first few weeks of pregnancy (Figure 5.13). Early ectopic sacs can be treated by injection of potassium chloride or methotrexate under ultrasound guidance. This approach is especially useful in IVF programmes where sparing the uterine tubes is important.

Infections

Ultrasound is useful in the diagnosis and management of ovarian abscesses, where shaggy walled cavities can be demonstrated in the adnexal region (Figure 5.14). They usually have a vascular pseudocapsule that can be demonstrated on colour Doppler. However, in pelvic inflammatory disease without abscess formation, the ultrasonic changes are too subtle to make this a useful technique. Monitoring the effects of antibiotic treatment on tubo-ovarian abscesses may be useful, although, in some cases, sterile cavities persist for

Figure 5.13 Ectopic gestation. In this transvaginal scan, colour signals are seen around the ectopic sac using power Doppler.

Figure 5.14 Tubo-ovarian abscess. The irregular walls of this cavity are vascularized as part of the inflammatory response.

many weeks after signs of infection have been controlled. The hydrosalpinx that complicates pelvic inflammatory disease is seen as a funnel-shaped cavity in the adnexal region with thin walls and no internal echoes.

Venous thrombosis

Diagnosis

A relatively common complication of pregnancy and gynaecological malignancies, deep venous thrombosis is most easily diagnosed using colour Doppler ultrasound and this should be the investigation of first choice. Visualization of the iliac veins may be difficult and some patients will have to proceed to contrast venography. If colour Doppler ultrasound has shown the femoral veins to be clear of thrombus, this is most easily performed by puncturing these vessels directly, which allows excellent opacification of the iliac veins and thus a confident diagnosis or exclusion of thrombosis, which can be difficult when contrast is injected into foot veins.

Inferior vena cava filter insertion

The indications for insertion of an inferior vena cava filter are listed in Box 5.1. The procedure is easily performed via femoral or jugular venous punctures, and some devices may even be inserted through a sheath introduced into an antecubital fossa vein. The majority of these filters are inserted permanently; short-term placement is possible, however, and is most commonly indicated in the late stages of pregnancy (when free-floating thrombus is demonstrated or when a recent pulmonary embolus has occurred), or prior to surgical removal of a large pelvic tumour which has caused compression and thrombosis of one or both iliac veins. Two types of short-term filter may be used: temporary and retrievable.

- Temporary filters are mounted on a long catheter and are placed via an internal jugular or antecubital fossa venous approach into the infrarenal inferior vena cava

Box 5.1 Indications for inferior vena cava filter placement

- Recurrent pulmonary emboli despite anticoagulation
- Pulmonary embolic disease in a patient in whom anticoagulation is contraindicated
- Free-floating pelvic or inferior vena caval thrombus
- Prophylaxis during surgery (see text)
- Previous life-threatening pulmonary embolism

above the thrombus (Figure 5.15). The device is then sutured in place. They can only be left *in situ* for approximately 10 days and should then be removed because of the risk of infection.

- Retrievable filters are designed for permanent placement and are inserted via an internal jugular venous approach. One such device is the Günther Tulip filter (William Cook Europe, Bjaeverskov, Denmark) which has a hook on its superior aspect. This may be grasped with a loop snare and withdrawn into a sheath prior to its removal. These devices can be removed after 10 days, but this is associated with more potential complications as some endothelialization of the filter is likely to have occurred at this time and the filter limbs may be partially fixed to the caval wall.

Haemorrhage

Haemorrhage from the genital tract may complicate parturition or may be associated with benign (e.g. uterine arteriovenous malformation) or malignant (e.g. cervical carcinoma) disease. Traditional surgical therapy of severe pelvic haemorrhage consists most commonly of unilateral or bilateral internal iliac artery ligation, although in the case of primary postpartum haemorrhage, hysterectomy is more often performed.

There is a strong argument in favour of angiography and embolization prior to arterial ligation or hysterectomy in

Figure 5.15 Temporary vena caval filter insertion above free-floating thrombus. (A) Control film. (B) Inferior vena cavogram using digital subtraction demonstrates a large free-floating thrombus. (C, D) A temporary filter has been placed on top of the thrombus using a right internal jugular approach. The plastic catheter on which the filter is mounted is barely visible.

Figure 5.16 Severe postpartum haemorrhage in a patient who had been explored twice vaginally and who continued to bleed in spite of vaginal packing. (A) Control film showing a large pack in pelvis. (B) Selective internal iliac arteriogram demonstrates brisk extravasation of contrast from a branch of the anterior division. This was selectively catheterized and occluded with polyvinyl alcohol particles. (C) Postembolization arteriogram demonstrates occlusion of the bleeding vessel with no further extravasation of contrast.

hospitals having the necessary expertise. Bleeding sites are often impossible to localize at surgery (hence the necessity for non-specific ligation of the internal iliac artery), but are usually easily identified at angiography; selective occlusion of the haemorrhaging vessel can then be performed with a much higher likelihood of controlling bleeding (Figure 5.16). Previous internal iliac artery ligation does not necessarily prevent successful arterial embolization but may make the procedure technically more difficult (Collins and Jackson 1995).

Embolization is very successful in a variety of gynaecological disorders complicated by bleeding. For certain conditions (e.g. uterine arteriovenous malformations, bleeding from recurrent cervical carcinoma), this should be considered as the procedure of first choice (Figure 5.17). In others, it may be life-saving when more conventional treatment has failed.

Cervical carcinoma

The cervix

In cervical carcinoma, precise staging of the primary disease provides a prognosis, allows the institution of correct treatment and permits comparison of different treatment proto-

cols. Clinical staging, applied according to the system of the International Federation of Gynecology and Obstetrics, is subjective and is still widely used. Imaging with ultrasound does not improve the accuracy of clinical staging (Fotopoulou et al 2008), with poor image quality and difficulty in interpretation as the major problems. Although transrectal ultrasound produces clearer views of the cervix, definition of tumour from normal cervix is still poor. The same difficulty limits the value of CT because the normal cervix and cervical carcinomas have similar attenuation values, so the tumour can only be recognized if it alters the contour or size of the cervix (Subak et al 1995). MRI is now widely recognized as the staging modality of choice.

Several studies confirm the accuracy of MRI in the staging of early cervical cancer in comparison to surgical staging (Whitten and deSouza 2006). The primary tumour is best assessed using T₂-weighted MRI, which is superior to CT in detection (sensitivity 75% vs 51%, $P < 0.005$) and staging (accuracy 75–77% vs 32–69%, $P < 0.025$) (Kim et al 1993, Ozsarlak et al 2003).

The resolution of the primary tumour on MRI may be further improved by using intracavitary receiver coils. Endorectal coils give high-resolution images of the posterior cervix, but the anterior margin of the tumour and its relation to the bladder base is often difficult to define because

Figure 5.17 Embolization of an area of neovascularity in the right side of the pelvis due to recurrent carcinoma of the cervix in a patient with persistent bleeding. (A) Selective right internal iliac arteriogram using digital subtraction shows encasement of the origin of the right uterine artery which supplies an extensive area of neovascularity. (B) The right uterine artery has been selectively catheterized prior to embolization. Note the marked irregularity of this vessel due to involvement by tumour. Embolization performed with polyvinyl alcohol particles gave excellent control of bleeding.

of drop-off of signal. Endovaginal coils give very-high-resolution images of the cervix and adjacent parametrium (deSouza et al 1996). The distortion of the low-signal ring of inner stroma may be apparent, and any breaks in the ring representing tumour extension may be identified (Figure 5.18A,B).

With MRI, the invasion of cervical cancer may be assessed in three planes: the coronal and axial planes are used for determining parametrial invasion, the axial plane is used for determining extension into the bladder and rectum, and the sagittal plane is used for extension into the uterine body, bladder and rectum (Sala et al 2007). Fast spin-echo T_2 -weighted sequences provide the best image contrast (Figure 5.19). MRI is also accurate in the prediction of myometrial tumour involvement and in showing the relationship of the tumour to the internal os, and hence the patient's suitability for trachelectomy (Peppercorn et al 1999). Volume (three-dimensional) imaging also provides the information necessary to calculate tumour volumes, which is of prognostic significance. Volumes obtained with MRI correlate well with those obtained by histomorphometric methods, but only weakly with clinical stage (Burghardt et al 1989). The volumetry of the tumour also gives a more accurate prediction of parametrial invasion and lymph node involvement (Burghardt et al 1992). Measuring tumour volume on MRI is of paramount importance; it has been shown that it is the size of tumour burden that determines the outcome rather than invasion beyond the anatomical margins of the uterus (Soutter et al 2004). Dynamic contrast-enhanced studies have been used for assessment of tumour angiogenesis (Hawighorst et al 1999), and the rate of contrast uptake has

been shown to correlate with microvessel density in the tumour. However, no correlation with tumour aggressiveness has been demonstrated (Postema et al 1999) and these images are not used routinely. Recently, diffusion-weighted MRI has shown higher accuracy than T_2 -weighted imaging alone for tumour detection (Charles-Edwards et al 2008).

Parametrium

CT and MRI have both been used to assess parametrial spread. False-positive diagnoses may arise from misinterpreting inflammatory parametrial soft tissue strands associated with a tumour as actual tumour invasion on both CT and MRI. A comparison of the assessment by these modalities with histological findings after radical hysterectomy showed an accuracy rate for parametrial involvement of 87–90% for MRI, 55–80% for CT and 82.5% for examination under anaesthesia (Kim et al 1993). Extracervical extension on MRI is best defined using T_2 -weighted fast spin-echo sequences transverse to the cervix (deSouza et al 1998). Fat-suppression techniques do not provide additional benefits (Lam et al 2000). Contrast enhancement has not proved beneficial; in a series of 73 patients, fast spin-echo T_2 -weighted images had an accuracy of 83% for determining parametrial extension (compared with 65% for T_1 -weighted gadolinium-enhanced images and 72% for T_1 -weighted gadolinium-enhanced fat-suppressed images). The high negative predictive value (95%) for the exclusion of parametrial tumour invasion was the principal contributor to the staging accuracy obtained with fast spin-echo T_2 -weighted imaging (Sironi et al 2002). MRI therefore yields valuable informa-

Figure 5.18 Carcinoma of the cervix: (A) T₁-weighted (SE 780/20) and (B) T₂-weighted (SE 2500/80) transverse spin echo through the cervix showing a large intermediate-signal-intensity mass mainly on the left. There is distortion and displacement of the normal low-signal band of inner stroma (arrows). A break in this stromal ring indicating parametrial extension is seen on the T₂-weighted images (arrowhead in B).

Figure 5.19 Carcinoma of the cervix: a sagittal magnetic resonance image using a newly developed double inversion recovery sequence through the pelvis. A large carcinoma is seen (arrows) abutting but not invading the bladder base anteriorly and the rectal wall posteriorly. The uterus lies immediately cranial (large arrow).

tion for treatment planning and should be used routinely in conjunction with clinical staging to determine the appropriate therapy in patients with cervical carcinoma.

An intravenous urogram is now obsolete as part of the staging process as it has been superseded by MRI.

Nodal involvement

The role of lymphangiography in the staging of cervical cancer is obsolete, with up to 71% false-positive results

Figure 5.20 Computed tomography scan of stage IIIb cervical carcinoma.

and 16% false-negative results. Percutaneous fine-needle aspiration biopsy of nodes had been used to improve the results obtained with pelvic lymphangiography, but this has been replaced by CT. The major drawback for epithelial tumours is that nodes must be enlarged to be detectable. Thus, metastases less than 2 cm in diameter will not be identified.

Some studies have shown an improvement in pelvic lymph node evaluation with MRI compared with CT (accuracy 88% vs 83%, $P < 0.01$) (Kim et al 1993). However, like CT, this relies on changes in the size of the lymph nodes (Figure 5.20) since the tumour deposits themselves are not highlighted.

A lymph-node-specific MR contrast agent has been developed that allows the identification of malignant nodal infiltration independent of the lymph node size. This novel

MR contrast agent is classified as a nanoparticle (mean diameter 30 nm), and is composed of an iron oxide core, coated with low-molecular-weight dextran (ultrasmall particles of iron oxide, USPIO). The particles, administered intravenously, are taken up by macrophages in the reticuloendothelial system, predominantly within the lymph nodes. Uptake of USPIO results in marked loss of signal intensity (darkening) of the node on T_2 - and T_2^* -weighted sequences because of a susceptibility artifact caused by the iron. Metastatic tissue within a node displaces the normal macrophages, thus preventing uptake of contrast agent, and the node continues to remain high in signal intensity. A significant increase in sensitivity with no loss of specificity has been demonstrated for the detection of malignant lymph nodes with USPIOs in patients with cervical and endometrial cancer (Rockall et al 2005). On a node-by-node basis, the sensitivity increased from 29% using standard size criteria to 93% using USPIO criteria. On a patient-by-patient basis, sensitivity increased from 27% using standard size criteria to 100% using USPIO criteria.

The role of positron emission tomography (PET) for detecting metastatic pelvic lymph nodes remains unproven. Small single-centre studies claim 91–96% sensitivity and 96–100% specificity for detecting nodes involved with tumour (Reinhardt et al 2001, Loft et al 2007), while results from other studies are much poorer (Williams et al 2001). Urinary residues of ^{18}F FDG in the ureters remain a source of false-positive results. Quantitation suggests that a $\text{SUV}_{\text{max}} \geq 3.3$ for lymph nodes is a significant adverse factor in those patients with nodal enlargement (Yen et al 2008).

Distant spread

Even with advanced pelvic spread, involvement of distant sites is the exception rather than the rule. Patients with stage I and II cervical cancer do not need to have bone scans.

A chest X-ray is a routine pretreatment investigation, but the yield of lung metastases at first presentation is likely to be no more than 2%.

Assessing response and recurrence

In conjunction with clinical examination, MRI can provide an objective assessment of the effects of surgery or radiotherapy. Serial MRI may be used before and after primary radiation therapy to assess tumour response (Akin et al 2007), and is increasingly important with the increased use of cytotoxic regimes. CT and ultrasound have limited ability to differentiate between fibrosis and tumour. While some say that infiltration of the parametrium may be easily recognizable, it is difficult to differentiate fibrosis after treatment from tumour recurrence. The use of contrast agents in detecting recurrent disease has proved disappointing; overall, diagnosis is best with unenhanced T_2 -weighted images, but particularly in patients with treatment complications (e.g. fistula formation), contrast enhancement does help (Hricak et al 1993).

PET-CT is increasingly used in identifying pelvic recurrence with sensitivity, specificity and accuracy of 92.0%, 92.6% and 92.3%, respectively (Kitajima et al 2008). PET-CT is also able to detect lung metastasis, local recurrence, peritoneal dissemination, para-aortic lymph node metastasis and pelvic lymph node metastasis, and is a useful comple-

mentary tool for obtaining good anatomical and functional localization of sites of recurrence during follow-up of patients with cervical cancer.

Endometrial carcinoma

Primary tumour

Thickening of the endometrium is characteristic of endometrial carcinoma and is well demonstrated on transvaginal ultrasound (Figure 5.21). However, specificity is low, although Doppler may help to distinguish hormonal causes of thickening (weak signals) and malignancy which gives marked colour and spectral Doppler signals (Weber et al 1998). Three-dimensional power Doppler has been reported to improve detection of endometrial carcinoma in patients with postmenopausal bleeding (Alcazar and Galvan 2009).

In patients already proven to have an endometrial cancer, myometrial extension has important prognostic and therapeutic implications. Myometrial invasion may be classified as absent, superficial or deep, and this can be assessed with high-resolution ultrasound probes. In a study of 75 patients, ultrasound had a diagnostic accuracy of 73% (Berretta et al 2008). Errors occurred when the tumour was exophytic and had significant extension into the uterine cavity. False-positive results also occur if the uterine cavity is distended with pus or blood when a subendometrial hypoechoic halo may be seen. Ultrasound assessment of the integrity of the echopoor layer can be improved by the use of transvaginal or transrectal sonography. However, ultrasound has been superseded by MRI.

Changes in uterine blood flow have been used to detect endometrial cancer using endometrial thickness (including tumour), and the pulsatility index (PI) derived from flow velocity waveforms recorded from both uterine arteries and from within the tumour (Bourne et al 1991) found an overlap in endometrial thickness between women with endometrial cancer and those without, but the PI was invariably lower in women with postmenopausal bleeding caused

Figure 5.21 Transvaginal ultrasound image of cystic hyperplasia of the endometrium. The grossly thickened endometrium is clearly seen, together with the cystic spaces, in this patient on tamoxifen.

by endometrial cancer than in those with other reasons for bleeding. Blood flow impedance is inversely related to the stage of the cancer. However, although PI values in healthy women increase slightly with age, they decrease with oestrogen replacement therapy, so although Doppler studies may be helpful in the detection of endometrial cancer, allowance must be made for oestrogen replacement therapy.

CT has been used to stage endometrial cancer which is seen as a hypodense lesion in the uterine parenchyma (Hardesty et al 2001), or as a fluid-filled uterus due to

tumour obstruction of the endocervical canal or vagina. These findings, however, are non-specific and are easily confused with leiomyomata, intrauterine fluid collections and extension of a cervical carcinoma into the uterine body. In addition, a central lucency may occur in normal postmenopausal women.

MRI represents the best method of assessing a patient with an endometrial cancer, with advantages over other radiological techniques. Figure 5.22 is a series of MRI scans of patients with endometrial cancer. On the T₂-weighted pulse sequence,

Figure 5.22 Magnetic resonance imaging scans (T₂) of two patients with endometrial cancer. The sagittal (A) and transverse (B) views in the first patient show tumour filling the endometrial cavity (arrows), but the surrounding low-signal-intensity junctional zone is intact. In the second patient, the sagittal (C) and transverse (D) views show tumour filling the endometrial cavity (arrows) with breach of the low-intensity junctional zone (arrowheads) and extension of tumour into the myometrium.

the tumour has a signal intensity similar to that of normal endometrium, but showing some degree of variability. The high signal makes the tumour quite distinct from the surrounding myometrium, which possesses an intermediate-signal intensity. In a premenopausal uterus, however, it may be difficult to differentiate tumour from adenomatous hyperplasia or indeed from the high signal of normal endometrium. Contrast-enhanced T_1 -weighted MRI improves the ability to assess the depth of myometrial invasion by endometrial tumour (Koyama et al 2007, Sala et al 2009). MRI has been found to have a sensitivity of 57% and a specificity of 96% for tumour confined to the endometrium, a sensitivity and specificity of 74% for superficial invasion, and a sensitivity and specificity between 83–88% and 72–85%, respectively, for deep penetration (Sironi et al 1992, Cabrita et al 2008). However, the degree of invasiveness may be overestimated for exophytic polypoid tumours with significant extraluminal extension (Chung et al 2007, Sanjuan et al 2008). Powell et al (1986) first described the low-signal band of inner myometrium to be thinned or absent in those patients with deeply invasive tumours, and this correlated well with the pathological measurement of myometrial invasion.

The sagittal plane is the most appropriate for examination of a patient with primary endometrial cancer, as this provides a longitudinal view of the uterus which will include both corpus and cervix. Using the sagittal plane also provides the opportunity to assess anterior invasion of the tumour into the bladder and posteriorly to the rectum. Critical review and expert consensus of MRI protocols by the European Society of Urogenital Radiology, from 10 European institutions, and published literature between 1999 and 2008 indicated that high-field MRI should include at least two T_2 -weighted sequences in sagittal, axial oblique or coronal oblique orientation. High-resolution post-contrast images acquired at 2 min \pm 30 s after intravenous contrast injection are optimal for the diagnosis of myometrial invasion. If cervical invasion is suspected, additional slice orientation perpendicular to the axis of the endocervical channel

is recommended. Due to the limited sensitivity of MRI to detect lymph node metastasis without lymph-node-specific contrast agents, retroperitoneal lymph node screening with precontrast sequences up to the level of the kidneys is optional. The likelihood of lymph node invasion and the need for staging lymphadenectomy are indicated by high-grade histology at endometrial tissue sampling and by deep myometrial or cervical invasion detected by MRI (Kinkel et al 2009).

FDG-PET has been shown to display a higher sensitivity (96.7%) than CT/MRI (83.3%) for identifying primary and extrauterine (83.3% vs 66.7%) lesions, although no difference in specificity emerged between the two modalities (both 100%) (Suzuki et al 2007). For lymph node evaluation, MRI and FDG-PET are equivalent — sensitivity (91.5% vs 89.4%), specificity (33.3% vs 50.5%), accuracy (84.9% vs 84.9%), positive predictive value (91.5% vs 93.3%) or negative predictive value (33.3% vs 37.5%) (Park et al 2008) — which does not justify the use of PET-CT in disease staging.

Recurrent disease

Transrectal sonography has been investigated in cases where recurrent endometrial cancer is suspected (Savelli et al 2004). Physical examination may be difficult because of postsurgical fibrosis. Infiltration into the surrounding connective tissues and organs such as the rectum and bladder can be identified, and transrectal ultrasound can be used to guide transvaginal or transperineal fine-needle biopsy. As with recurrent cervical cancer, CT, MRI or PET-CT may be used to detect recurrent disease and metastatic carcinoma to omentum or lymph nodes.

Choriocarcinoma

Choriocarcinomas (gestational trophoblastic tumours) are characteristically hypervascular and this can be detected with colour Doppler (Figure 5.23) (Sebire and Seckl 2008). On spectral Doppler, they have a very low resistance index and this is useful for monitoring response to chemotherapy,

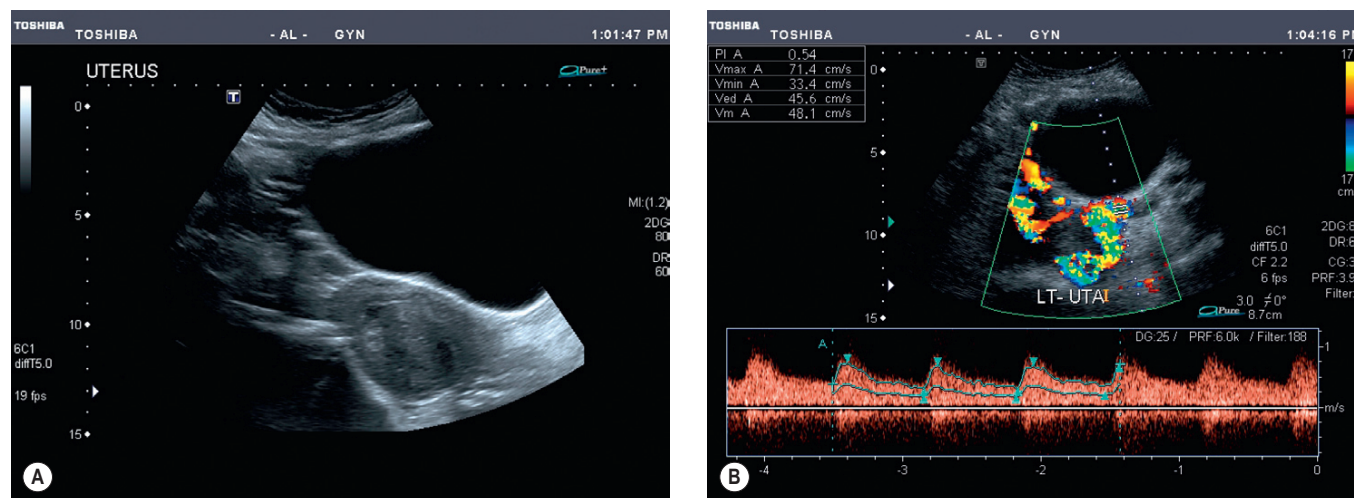

Figure 5.23 Choriocarcinoma. A bulky uterus of non-specific pattern was seen on grey-scale ultrasound of this choriocarcinoma (A). (B) The colour Doppler study shows the marked tumour vascularity. The spectral Doppler sample volume has been placed over the left uterine artery and reveals fast flow with minimal pulsatility, indicating lack of normal resistance to flow. This results in a low pulsatility index, changes in which can be used to monitor response to treatment.

Figure 5.24 Ultrasound scan of ovarian tumours. The smooth walls and echo-free contents of the benign cystic mass in (A) (arrowhead) are very different from the complex appearance of the 10.5 cm carcinoma in (B). The second cyst in (A) contains uniform low-level echoes, probably representing debris.

although ultrasound is not very sensitive in their initial diagnosis since the characteristic snow-storm appearance of the multiple cystic spaces is only present in 40% of cases.

Ovarian carcinoma

In patients with ovarian cancer, the dramatic difference in cure between patients with local disease (80–90%) and distant disease (15–25%) means that imaging to detect ovarian cancer early is desirable.

The ovary

Ultrasound has been explored as a screening method for carcinoma of the ovary in an attempt to detect early disease (Menon and Jacobs 2000, Sato et al 2000). Early studies demonstrated a poor yield: out of 5479 women screened, five women with primary stage I cancer and four women with metastatic disease of the ovary were diagnosed (Campbell et al 1989). The overall rate of false-positive results was 2.3% and the likelihood of a positive scan being a primary ovarian cancer was one in 67. A scoring system has been evolved which reduces the number of false-positive results which otherwise occur due to confusion with unusual-appearing corpora lutea and benign tumours (Timmerman et al 1999). The improved resolution of transvaginal scanning permits a more detailed morphological examination (Figure 5.24A,B). This has been tested in a study of 25,000 asymptomatic postmenopausal women, of whom 740 had raised CA125 levels and were referred for ultrasonography; an ovarian volume of 8.8 ml was used as a cut-off for normality. All 20 cancers had abnormal morphology consisting of complex cysts, although there were numerous false-positive results. The positive predictive value was approximately 20% (Menon et al 2000).

Benign lesions are unilocular or multilocular with thin septae and no nodules, whereas malignant lesions are often multilocular with thick septae and nodules. The use of transvaginal colour flow imaging has been advocated, but these studies have been variously reported as disappointing or useful (Varras 2004). Initially, a low resistance index (less than 0.4) was advocated as the best discriminator, but this has proved unreliable and a high peak velocity may be a

better feature. At present, the role of ultrasound in screening, although attractive, remains unvalidated (Partridge et al 2009) and the results of larger trials are awaited. Additional specificity might be gained by adding contrast agents.

In ovarian cancer staging, MRI and CT are more sensitive than ultrasound (95%, 92% and 69%, respectively) for detecting peritoneal metastases, especially in the subdiaphragmatic spaces and hepatic surfaces (Tempany et al 2000). Either modality therefore can be used to stage advanced ovarian cancer. The potential of PET to identify metabolically active tumour that does not appear on morphological studies is promising. In one study, the PET-CT scan indicated a different disease distribution compared with CT alone in 55% of patients, and changed therapeutic management in 34% (Soussan et al 2008). Therefore, although current evidence for its utility is limited, PET-CT may be of major importance in staging ovarian cancer in the future.

As a tumour arising from a non-essential organ that is initially confined to the peritoneal cavity, ovarian cancer makes an attractive target for monoclonal antibodies. An antibody to CA125 has been assessed in monitoring the course of the disease (Sok et al 2009). However, antibodies are often limited by problems that include antibody specificity, stability and immunoreactivity, as well as patient reaction to the antibodies used. Antibodies coupled to drugs or biological toxins are also under investigation. Some antibodies may have direct antitumour effects through binding to biologically active receptors or through immune receptor functions. The use of antibody fragments, chimeric antibodies and genetically engineered antibodies is also under active investigation (Badgwell and Bast 2007).

Pelvic and abdominal spread

CT is the most useful imaging modality for demonstrating macroscopic recurrence, and can spare patients a second-look laparotomy. A variety of manifestations can be seen with CT, each of which can have a spectrum of appearances including ascites, peritoneal seeding, and visceral and nodal metastases (Forstner 2007). Ultrasound may also be used to detect ascites and liver metastases. MRI should be

Figure 5.25 Magnetic resonance imaging scans (T_2) of two patients with ovarian cancer. Sagittal views show a predominantly cystic mass in (A) with a solid component around the rim of the tumour. In (B), the mass is largely solid with a small cystic component.

performed in women with questionable macroscopic recurrent tumour and negative CT examination (Figure 5.25), although neither modality can exclude microscopic disease. Newer whole-body diffusion-weighted MRI measurements are looking extremely promising in identifying peritoneal spread (Kyriazi et al 2009). PET-CT may also prove to be of benefit, although quoted accuracy reflects local expertise at image interpretation: lesion-based sensitivity and accuracy of FDG-PET/CT vs MRI has been recorded as 43% and 86%, and 75% and 94%, respectively ($P < 0.05$) (Kim et al 2007), indicating that FDG-PET/CT is not as useful as MRI for detecting local pelvic recurrence and peritoneal lesions in ovarian cancer recurrence. In contrast, in a recent meta-analysis of 34 studies comparing CA125, PET alone, PET-CT, CT and MRI, PET-CT had the highest pooled sensitivity (0.91, 95% confidence interval 0.88–0.94). The area under the curve (AUC) was 0.9219, 0.9297, 0.9555, 0.8845 and 0.7955, respectively. Results of pairwise comparison between each modality demonstrated that AUC of PET, whether interpreted with or without the use of CT, was higher than that of CT or MRI ($P < 0.05$) (Gu et al 2009).

Immunoscintigraphy of ovarian cancer lesions has been performed mainly with ^{99m}Tc , ^{111}In and ^{123}I labelled with HMFG1, HMFG2, OC-125, B72.3, H17E2, OVTL3, MoAb170, Mov18 and other monoclonal antibodies (MoAbs). Improved targeting has resulted in a highly sensitive and specific method. However, it is not yet known which type of MoAb most usefully supplements conventional diagnostic methods in staging or measurement of treatment response (Kalofonos et al 2001).

Safety Issues

Although the majority of imaging procedures described are largely non-invasive, some modalities involve exposing the

patient to ionizing radiation. This is one of the reasons why techniques such as ultrasound and MRI have received so much attention in obstetrics and gynaecology. Nevertheless, ultrasound necessitates irradiation of the patient with sound waves (mechanical vibrations), and MRI involves the application of strong and rapidly changing magnetic fields combined with radio waves. Careful studies have failed to reveal harmful effects from the clinical use of ultrasound or MRI investigations, but each modality has an associated risk which must be appreciated.

With ultrasound and MRI, the main biological effect is of the conversion of the interrogating source of energy (sound, magnetic flux, radio waves) into heat. The American Institute for Ultrasound in Medicine has issued the following guidelines: 'In the low megahertz frequency range there have been no demonstrated significant biological effects of ultrasound in mammalian tissues exposed in vivo to intensities below 100 mW/cm^2 '. Higher powers do damage tissue (mainly by heating, a feature used in physiotherapy), but at diagnostic levels the heating is minimal and removed continuously by the blood circulation. Spectral Doppler delivers the highest intensity, and this is compounded by the fact that the beam is trained on to a target for longer periods of time than in imaging. It seems prudent to restrict scanning, especially spectral Doppler, to genuine clinical indications and to use it for the shortest time and at the lowest intensity needed to make the diagnosis.

As early as 1896, reports were made of a visual sensation of light flashes induced by exposure to changing magnetic fields. However, the main hazards associated with rapidly changing magnetic fields are those from magnetic implants. Patients with cardiac pacemakers or aneurysm clips constitute an absolute exclusion to being scanned. Other metallic implants must be considered on an individual basis. Other hazards arise from electroconvulsion and atrial fibrillation, hence caution should be exercised with epileptic patients

and those who have recently suffered from myocardial infarction. Guidelines for the use of MRI have been laid down by the National British Radiological Protection Board (1984).

Before deciding to carry out any imaging investigation, however, a clinical decision has to be made concerning whether the benefits accrued from the results of the investigation outweigh any possible risk to the patient from the procedure to be undertaken.

Conclusions

Advances in medical imaging are occurring at a rapid rate, mainly due to the development of sophisticated imaging

techniques, computer software and display systems. Ultrasound, with its flexibility and relatively low cost, retains an integral diagnostic role in gynaecology, with transvaginal sonography a routine adjunct to a bimanual pelvic examination. MRI provides superior soft tissue contrast of the pelvic organs and leads to an increase in detection, improved staging and assessment of a range of disease processes including cancer. The technology needed to overcome the major disadvantages of long scanning times and claustrophobic scanners is well advanced. MR spectroscopy remains largely unexplored in gynaecology, but is an exciting prospect for the future. The various imaging modalities are complementary to each other, and the appropriate choice to produce the greatest diagnostic return while minimizing the risk to the patient should be sought.

KEY POINTS

1. Ultrasound examination is dependent upon both the technical expertise of the ultrasonographer and an understanding of the patient's history and clinical findings.
2. Ultrasound is the technique of choice for imaging the endometrial cavity and the ovaries, but it cannot distinguish reliably between benign and malignant disease.
3. Ultrasound is very valuable in monitoring ovulation induction and is used in directing egg collection for IVF.
4. Ultrasound can be valuable in identifying an ectopic gestation.
5. MRI gives the best images of endometrial carcinoma and adenomyosis. It may identify endometriosis that cannot be visualized in any other way.
6. MRI is the best method for imaging cervical carcinoma, especially when an endovaginal receiver coil is used. Imaging of pelvic lymph nodes is still not reliable.
7. CT scanning is of limited value in assessing the pelvic organs and should probably not be used if MRI is available.
8. Radionuclide imaging can be of value in identifying and locating ovarian carcinoma.
9. Angiographic embolization is probably the treatment of first choice for postoperative pelvic haemorrhage.
10. Negative lymph nodes on FDG-PET are not a justification for omitting retroperitoneal lymph node dissection for the precise surgical staging of gynaecological cancers.

RESOURCES FOR SERVICES	81	CONCLUSION	90
THE EMERGENCY GYNAECOLOGICAL UNIT	81	KEY POINTS	90
ULTRASOUND OVERVIEW	82		

Introduction

Acute gynaecological symptoms such as pelvic pain and bleeding occur in pregnant women who have miscarriages, ectopic pregnancies and pregnancies of unknown location, or in women who are not pregnant with ovarian cyst accidents or acute pelvic inflammatory disease. The investigation of the acute gynaecological patient is moving away from the accident and emergency department and operating theatre, and into dedicated emergency gynaecology units (EGUs) located in an outpatient setting (Jones and Pearce 2009). EGUs offer an efficient way of organizing multidisciplinary services for women presenting with acute gynaecological symptoms. These changes have been driven by the demands of the patient and clinician to provide a rapid, accurate diagnosis, with the minimum of investigations and invasive procedures. They are underpinned by national standards and guidelines (Department of Health 2003, Royal College of Obstetricians and Gynaecologists 2006). Furthermore, changing from traditional care pathways to more cost-effective, patient-centred approaches to medical practice lies at the heart of modern health service management (Department of Health 2000, Jones 2008).

In the UK, the majority of gynaecological ultrasound scanning has traditionally been undertaken by radiographers and radiologists in a separate department on a separate day. Transvaginal ultrasonography (TVUS) is a pivotal investigation for the assessment of acute gynaecological patients. Therefore, in order to deliver modern acute gynaecological services, gynaecologists will have to learn these new skills (Jones 2005). TVUS probes, providing high-resolution images of the pelvic organs, have an established role in the characterization of adnexal masses, providing reliable and reproducible information regarding cyst type and probability of malignancy (Granberg et al 1989, 1990, Tailor et al

1997, Timmerman et al 1999a), particularly when they are used in combination with tumour markers (Moore et al 2008). They have superiority over transabdominal probes because of the higher resolution of pelvic anatomy. There is also no need for a full bladder, improving patient acceptability.

TVUS is a pivotal investigation in the delivery of an 'Ambulatory Gynaecology Service' (Jones 2008). This is a more comprehensive term which would include the assessment of patients with non-acute gynaecological symptoms such as menstrual disorders, postmenopausal bleeding and chronic pelvic pain. The discussion of these conditions falls outside the scope of this chapter.

The accurate identification of pathology on ultrasound will enable the clinician to plan the patient's management effectively. The ultrasound diagnosis may determine if the patient is suitable for minimal access surgery or they may need a laparotomy and a multidisciplinary oncology team. In this way, preoperative ultrasound assessment of the patient will improve patient counselling and satisfaction with treatment.

This chapter deals with assessment of the patient presenting with acute symptoms, in whom gynaecological pathology is suspected. By adopting a problem-orientated approach, the aim is to provide a series of reproducible pathways allowing effective investigation of these patients. TVUS is central to all these diagnostic pathways but it should be regarded as an extension of the clinical examination; a normal scan will not exclude all underlying gynaecological conditions. The first part of this chapter will explore the place of TVUS in the differential diagnosis of acute pain and bleeding in early pregnancy. The second part of the chapter will give an overview of the role of pelvic ultrasound in the evaluation of acute pelvic pain and vaginal bleeding in women with a negative pregnancy test.

Resources for Services

Ultrasound machine

Most gynaecology units will already have an ultrasound machine that can be used within a clinic setting. Minimum requirements are a transvaginal probe (6–7.5 MHz), a 3.5 MHz abdominal transducer and facilities for capturing images, either as a hard copy or digitally. A portable machine can be a wise investment if it is to be shared, for example, with the delivery suite, or to allow for ultrasound-guided procedures in the operating theatre. The ultrasound machine should not be more than 5 years old (Royal College of Radiologists/Royal College of Obstetricians and Gynaecologists 1995).

Reducing the risk of infection transmission

TVUS is a relatively non-invasive procedure. There is, however, a moderate risk of transmission of infection as the probe comes into contact with mucous membranes. The risk of infection is reduced by the use of an appropriate cover for the transducer. It is estimated that up to 7% of covers will sustain perforations, and contamination of the probe may also occur on removing the cover after use (Jimenez and Duff 1997). As a result, appropriate cleaning of the transducer must occur between patients. Sterilization of the probe is not practical, and disinfection using a germicidal (e.g. 70% alcohol) cloth or spray, after first wiping off the gel, is effective. The probe is then left to air dry for at least 5 min. Basic hygiene measures, such as washing hands after each case and ensuring that contaminated gloves do not come into contact with the ultrasound machine, must be used to minimize cross-infection. There is no need for the routine use of antibiotics during ultrasound scanning.

Computer database systems

A number of commercial database systems exist for the storage of data, including digital images. This allows a written report to be generated immediately for the referring physician and patient, and easy access to previous images for comparison, for example after treatment of conservative management of ovarian cysts.

Resuscitation equipment

All gynaecological clinics should have adequate resuscitation equipment in good order. The clinic staff should have up-to-date training in its appropriate use.

Analgesia

TVUS is a well-tolerated procedure, even in women who present with acute pelvic pain. It does not require the routine use of analgesia. Basama et al (2004) demonstrated that TVUS was considered acceptable, and not painful, embarrassing or stressful in a study of 425 women undergoing TVUS in an emergency setting.

Interventional radiology in acute gynaecology

Gynaecologists have been slow to use interventional radiological techniques outside the setting of the assisted concep-

tion unit. However, angiographic embolization has now become accepted as the treatment of choice for potentially life-threatening obstetric and gynaecological haemorrhage, and selected interventional radiological techniques can be carried out in the outpatient setting with minimal morbidity and complication rates. It is particularly useful in patients in whom surgery is relatively contraindicated; for example, extensive previous abdominal surgery or during pregnancy.

Ultrasound-guided ovarian cyst aspiration

It is now possible to aspirate ovarian cysts transvaginally. A TVUS probe with a biopsy guide attached is placed in the vagina and the ovarian lesion is targeted. Under ultrasound control, a needle is then passed through the transvaginal probe and fluid is aspirated from the cyst or collection. The size of the needle is adjusted according to the predicted viscosity of the fluid. When serous-type fluid is being aspirated, an 18- or 20-gauge needle will suffice. If the ovarian cyst is easily accessible and thin walled, it may not be necessary to administer intravenous sedation to cover the procedure. However, if intravenous sedation is needed, a combination of midazolam (Hypnovel®, Roche, Welwyn Garden City, UK), fentanyl and metoclopramide (Maxolon®, Shire, Basingstoke, UK) titrated in small doses is usually sufficient.

It is important that the ovarian cysts are unilocular and thin walled if the technique is going to be successful and safe. Subtle, superficial, internal mural nodules or small papillary excrescences should be searched for meticulously because these features may indicate a malignant lesion, in particular a borderline tumour. With careful attention to ultrasound surveillance, cyst aspiration can be performed safely (Caspi et al 1996, Troiano and Taylor 1998). In 33–50% of cases, cyst aspiration will constitute definitive therapy. In other cases, cysts will recur and it is important to remember that cytology alone is not sufficiently accurate to exclude malignancy. Cyst recurrence after drainage is higher than if the capsule is removed (Balat et al 1996), but cyst fluid cytology is not always representative of the cyst wall pathology (Dietrich et al 1999).

Haemorrhagic cysts that do not resolve spontaneously or those that are symptomatic may be aspirated, usually via an 18- or 20-gauge needle, resulting in complete relief of symptoms.

Cyst aspiration in pregnant women is also feasible, and this technique is useful for functional cysts that become large and symptomatic (Khaw and Walker 1990). Cyst aspiration decreases the risk of rupture or torsion. Cysts that persist into later pregnancy are more likely to be serous or mucinous, and may be malignant. However, in some cases, it may be useful to aspirate the cyst and to remove it post partum. Such treatment may be warranted after careful assessment because surgical treatment for cysts in pregnancy is not without risk, with reported miscarriage rates between 2% and 35%.

The Emergency Gynaecological Unit

The provision of an EGU is now recognized as a gold standard service (Royal College of Obstetricians and Gynaecologists 2006). It provides an easily accessible outpatient area

with facilities for ultrasound-based assessment of pregnancy duration, viability and location. This allows the clinician to provide informed management and counselling of the patient in a setting which maximizes her privacy and comfort. The EGU should have a dedicated area for the triage, assessment and initial management of patients presenting with acute gynaecological disorders, including early pregnancy complications. There should be a separate area where the patient can change, a designated waiting area with toilet facility, and bed/trolley spaces to accommodate women who need to recline. An initial assessment of the clinical condition can be made and recorded on a preformed history sheet. The cost benefits of the EPU are well established (Bigrigg and Read 1991) as admission can be avoided in approximately 40% of patients, with a further 20% requiring a shorter stay. Ideally, there should be a dedicated unit for the assessment and investigation of women with suspected complications of early pregnancy. This will be centred around an ultrasound scanning room, run by dedicated ultrasound practitioners. There should be a private area in which the patient can change and also a separate counselling room with access to a counselling service and outside line telephone.

Referral to the EPU may be by prior arrangement with the general practitioner or other consultant, or, ideally, a 'walk-in' self-referral system can operate. The latter will provide the patient with the means to contact a unit directly when problems arise, although it will make clinics busy. Again, the history can be collected on a proforma. This will highlight relevant gynaecological and obstetric history for the clinician, including factors predisposing to ectopic pregnancy or women in whom recurrent miscarriages have been identified, and will also facilitate audit and research. A number of computer databases now exist which aid data collection and facilitate reporting. This means that the patient can leave the clinic with a detailed report and follow-up plan, and a report can be distributed immediately to the referring clinician.

Many of the women who attend as gynaecological emergencies present with pelvic pain with or without vaginal bleeding. The differential diagnosis should be whether or not the symptoms have a gynaecological cause or some other underlying pathology, such as a gastrointestinal (e.g. constipation, appendicitis, diverticulities) or urological (e.g. urinary tract infection, stone) cause. If the symptoms are thought to be gynaecological in nature, the next decision is whether or not the woman is pregnant. If she is pregnant, pregnancy location and viability must be established. If the symptoms are not pregnancy related, are they chronic (>6 months' duration) or acute? If they are acute, does she have an ovarian cyst accident (e.g. haemorrhage, rupture, torsion) or acute pelvic inflammatory disease?

Availability of rapid serum β -human chorionic gonadotrophin (β -hCG) assays will vary within units, but the judicious use and follow-up of serum changes in β -hCG is essential for a diagnosis where the pregnancy location is not readily identified. This may be achieved in a number of ways, but typically will be dependent upon a dedicated staff member to record and interpret results either via a computer database or log book. The patient is either contacted with further follow-up/intervention plans or the patient contacts the unit herself for these results.

Fortunately, the majority of women with pain or bleeding in early pregnancy will present subacutely; in all cases, however, an initial assessment of haemodynamic compromise must be made. Blood pressure, pulse, temperature and pulse oximetry should be recorded. Facilities for obtaining venous access and commencing intravenous volume replacement should be available.

Anti-D immunoglobulin use

Current guidelines (Royal College of Obstetricians and Gynaecologists 2000 & 2006) for the use of rhesus immunoprophylaxis in early pregnancy recommend that anti-D immunoglobulin should be given to all non-sensitized rhesus-D-negative women who have:

- an ectopic pregnancy;
- a therapeutic termination of pregnancy (surgical or medical);
- a threatened or spontaneous miscarriage after 12 weeks' gestation (note: where there is heavy, recurrent or painful bleeding prior to 12 weeks' gestation, anti-D immunoglobulin prophylaxis is also recommended); or
- surgical evacuation of retained products of conception prior to 12 weeks' gestation.

Psychological aspects

Women, and their partners, who are diagnosed with early pregnancy failure should be offered follow-up to allow for appropriate support and counselling. This will facilitate early referral to formal counselling services when necessary.

Ultrasound Overview

TVUS should be regarded as an extension of a bimanual examination rather than a replacement. A recent prospective comparative trial of endovaginal sonographic bimanual examination versus traditional digital bimanual examination in non-pregnant women with lower abdominal pain has been reported (Tayal et al 2008). The study clearly demonstrated that vaginal examinations combined with TVUS improved confidence in key findings, such as ovarian and uterine size or position irrespective of the patient's body mass index. The advantages of TVUS over the transabdominal approach are well documented (Gonzalez et al 1988, Mendelson et al 1988). The placement of the ultrasound probe closer to the pelvic organs means that higher frequency ultrasound transducers (6–7.5 MHz) can be used, which produce high-resolution images. TVUS assessment of ovarian volume and morphology correlates closely with subsequent operative findings at laparotomy (Rodriguez et al 1988).

No single ultrasound measurement of the different anatomical features in the first trimester has been shown to have a high predictive value for determining early pregnancy outcome, and Doppler studies are not helpful either (Jauniaux et al 2005). Despite this, high-resolution TVUS has transformed understanding of the pathophysiology and management of early pregnancy failure. The ultrasound findings in both a normal pregnancy and a failing pregnancy are well described (Dogra et al 2005). The intrauterine gestation sac can be visualized from approximately 4 weeks after the

last menstrual period using a transvaginal transducer, which is approximately 2 weeks earlier than if using the transabdominal approach (Fossam et al 1988). This is dependent upon a regular 28-day cycle, and hence a more accurate approach to confirming pregnancy viability or failure is dependent upon either changes with time or the presence or absence of fetal cardiac activity. The diameter of the gestational sac increases at approximately 1 mm/day in early pregnancy (Nyberg et al 1985), and can be differentiated from the 'pseudosac' of ectopic pregnancy by its thick, echogenic rind surrounding the echo-lucent central chorionic sac and eccentric location to the endometrial midline. The presence of a normal intrauterine gestation sac is associated with β -hCG levels of >1000 IU. Detection at levels greater than this is dependent upon a number of factors, including type of probe and ultrasound machine used, the presence of leiomyomas, operator variations and multiple gestations (Nyberg et al 1985, Bernaschek et al 1988). The absence of a gestation sac should prompt the operator to look for an extrauterine gestation (including a close examination of the cornua and cervix as well as the adnexa). Visualization of the yolk sac is regarded as definitive evidence of an intrauterine pregnancy. The yolk sac can be visualized from 5 weeks' gestation (Figure 6.1), and the early embryonic pole from approximately 6 weeks. First recognized as a thickening along the yolk sac, it is linear to begin with, subsequently becoming curved in nature. The embryonic growth rate is 1 mm/day. Cardiac activity starts at approximately 5 weeks after the last menstrual period. Cardiac activity not detected in embryos of more than 4 mm is associated with embryonic demise (Brown et al 1990, Levi et al 1990, Goldstein 1992). However, a repeat scan to confirm diagnosis is always indicated. Embryonic bradycardia can be associated with poor outcome (Doubilet et al 1999), and a follow-up scan is warranted to confirm viability.

TVUS has an established role in the evaluation of adnexal masses. It provides an accurate assessment of ovarian morphology (Granberg et al 1989, 1990, Timmerman et al 1999b) and is a significant contributor to mathematical models being developed to assess ovarian tumours (Tailor et al 1997, Timmerman et al 1999a,c). There are several types of ovarian cyst that can be assessed using the recogni-

tion of characteristic morphological patterns (Jermy et al 2001). Endometriomas and benign cystic teratomas are two examples, accounting for over two-thirds of persistent adnexal masses in premenopausal women (Koonings et al 1989). These lesions can be particularly difficult to score using morphological scoring systems, and as angiogenesis is ubiquitous throughout the ovarian cycle, colour Doppler is of limited value (Alcazar et al 1997).

Clinical Conditions

Bleeding and/or pain with a positive pregnancy test

Sensitive urinary pregnancy testing kits, based on immunological assays, are able to detect β -hCG levels of between 20 and 50 IU with 99% accuracy. This has meant that an increasingly large number of women will present with bleeding and/or pain in early pregnancy. It has been estimated that approximately 30% of women will complain of pain or bleeding during early pregnancy, and approximately 15% of clinically recognizable pregnancies will result in miscarriage, the majority before the 13th week (Prendiville 1997). Due to the large volume of work in such a highly sensitive area of gynaecology, an integrated approach to diagnosis and management of women presenting with bleeding and/or pelvic pain during the first trimester is required.

With the judicious use of ultrasound, clinicians have the ability to alleviate anxiety concerning early pregnancy complications by accurately dating early pregnancy, confirming viability, diagnosing pregnancy failure, and either directly or indirectly confirming extrauterine gestation. To do this safely, knowledge of early pregnancy development, both ultrasonographically and biochemically, is pivotal.

Miscarriage

Once the diagnosis of intrauterine pregnancy has been established, the potential viability of the pregnancy will need to be addressed. The clinical value of the normal developmental timespan of the early embryonic and extraembryonic structures is its application in the diagnosis of pregnancy failure. What becomes more relevant is not the earliest point at which a structure can be seen (threshold), but the point at which a structure is always seen in a normally developing intrauterine pregnancy (discriminatory level), so its absence is diagnostic of pregnancy failure. Once an ectopic pregnancy has been excluded, all intrauterine pregnancies should be given the benefit of the doubt and serial scans should be performed to confirm a diagnosis. However, cardiac activity should always be visualized in an embryo measuring 6 mm or more (Figure 6.2).

Knowledge of early pregnancy anatomical landmarks allows one to follow fetal development within a normal pregnancy, and to establish safe guidelines in the diagnosis of a pathological pregnancy.

Terminology

- Missed miscarriage (early fetal demise): crown-rump length of at least 6 mm with no cardiac activity or no change in size on weekly serial scanning.

Figure 6.1 Intrauterine gestation and yolk sac: 5 weeks' gestation.

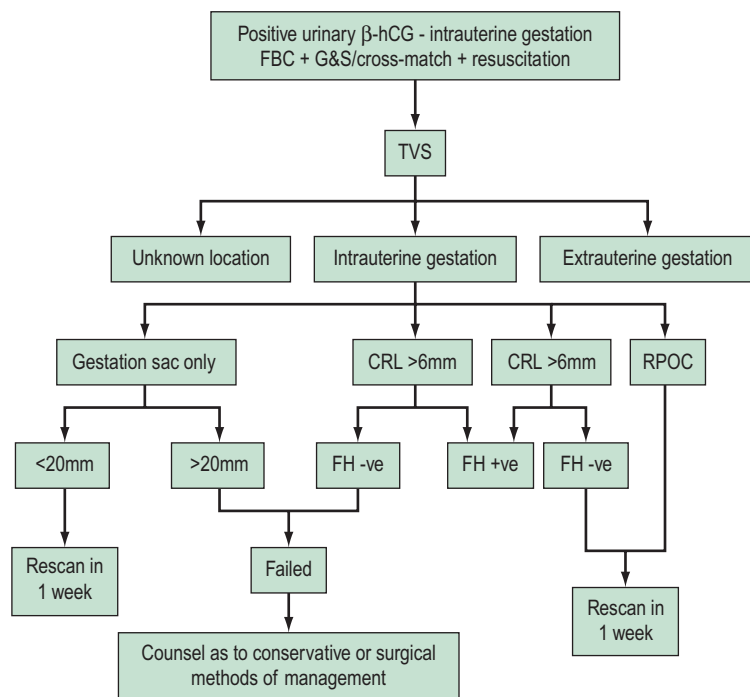

Figure 6.2 Assessment of viability in early pregnancy. β -hCG, β -human chorionic gonadotrophin; FBC, full blood count; TVS, transvaginal sonography; CRL, crown–rump length; RPOC, retained products of conception; G&S, groups and save; FH, fetal heart.

- Blighted ovum (early embryonic demise): mean diameter of gestational sac of at least 20 mm with no embryonic/extraembryonic structures present.
- Incomplete miscarriage: disrupted endometrial echo measuring >15 mm in the anteroposterior plane (Figure 6.3).
- Complete miscarriage: endometrial thickness of <15 mm measured in the anteroposterior plane associated with the cessation of heavy bleeding and pain.

Trouble shooting

- In practice, the presence of an intrauterine gestation usually excludes an ectopic pregnancy.
- Once ectopic pregnancy is excluded, early pregnancies should be given the benefit of the doubt; serial scans are of more value than serial β -hCG values.
- Cardiac activity should be seen with a crown–rump length of 6 mm or greater.
- A fetal pole/yolk sac should be seen with a gestation sac with a mean diameter of 20 mm.

Ectopic pregnancy

The exclusion of an ectopic gestation remains a primary goal for the clinician assessing a patient presenting with pain and/or bleeding in early pregnancy. Traditionally, the presence of an empty uterus with a positive urinary pregnancy test has meant hospital admission with either laparoscopy or follow-up scans until a diagnosis is made. However, the combined use of high-resolution vaginal probes and serum β -hCG assays has meant that patients with symptoms and clinical findings suggestive of an ectopic gestation will fall into one of three categories, as follows:

- an intrauterine pregnancy will be diagnosed on scan: to all extents and purposes, this will exclude an

Figure 6.3 Sagittal view of the uterus demonstrating retained products of conception.

extrauterine location. The frequency of heterotopic pregnancy in spontaneous conceptions is estimated at between 1:10,000 and 1:50,000, but is as high as 1:100 in assisted conceptions (Ludwig et al 1999), and should be suspected if there are persistent symptoms;

- an extrauterine gestation or highly predictive features (e.g. haemoperitoneum) will be visualized by ultrasound (Figures 6.4–6.6); or
- no evidence of intra- or extrauterine gestation will be found on scan alone; a pregnancy of unknown location.

Further management of the patient will be dependent upon her clinical status. Within the authors' unit, there has been a significant reduction in patients presenting with acute haemodynamic compromise due to a ruptured ectopic

Figure 6.4 Sagittal section of the left adnexa demonstrating a tubal ectopic pregnancy. The crown-rump length is marked (12.1 mm).

Figure 6.6 Sagittal view of the cervix containing a gestational sac, fetal pole and yolk sac. The proximal portion of the endometrial cavity contains free fluid and can be seen on the left side of the image.

Figure 6.5 Cornual ectopic pregnancy. The gestation sac is seen separately from the endometrial echo.

pregnancy since the EPU was established. This has meant that more conservative methods of treatment can be used, whether surgical (laparoscopic salpingectomy, salpingotomy), medical (methotrexate) or expectant (Figure 6.7).

All non-surgical methods of treating ectopic gestations will need intensive follow-up to ensure resolution of symptoms and β -hCG values. Patient compliance is central to these patients being treated on an outpatient basis, along with a dedicated EPU service (see Chapter 25, Ectopic pregnancy, for more information).

Pregnancy of unknown location

A proportion of women presenting with complications of early pregnancy will have no sonographic features of extra- or intrauterine pregnancy. This group will include patients who have a very early, continuing, intrauterine pregnancy, those who have an ectopic gestation and those who have a failing pregnancy, whether intra- or extrauterine. Rarely, a

false-positive result may be due to a placental site tumour, for example of the ovary. Figure 6.8 demonstrates a suggested follow-up regime for women who fall into this category. Again, a coordinated EPU and rapid β -hCG assay service are essential.

Coexistent pathology

The prevalence of ovarian pathology in early pregnancy is high; one advantage of TVUS is the ability to visualize the adnexa clearly in early pregnancy. The majority of adnexal pathology will be functional in nature, typically corpus luteal, and will spontaneously resolve as the pregnancy enters the second trimester. Whether or not surgical intervention is indicated for persistent, symptomatic cysts will be dictated on an individual basis, and the role of cyst aspiration and laparoscopic surgical techniques can be maximized when there is clear ultrasound definition of cyst type.

Those patients managed expectantly should be rescanned 6 weeks post partum to ensure cyst resolution or to arrange surgical intervention if there is persistence of the cyst.

Postnatal assessment

Few studies have targeted the normal ultrasound parameters of the uterus and ovaries in the postnatal period. The sonographic appearances of retained products of conception are variable (Carlan et al 1997, Hertzberg and Bowie 1991). One study evaluating the appearance of the uterine cavity revealed an echogenic mass in 51% of women with normal postpartum bleeding at 7 days post partum (Edwards and Ellwood 2000). Sonohysterography has been shown to enhance the ability of TVUS to diagnose retained products of conception (Wolman et al 2000), although in the presence of suspected pelvic infection, this procedure should not be performed. Management should be based primarily on clinical findings, with sonographic evaluation of the uterus and endometrium reserved for those cases with persistent symptoms. Rarely, arteriovenous malformations can cause protracted, heavy bleeding in the puerperium. If suspected, colour Doppler

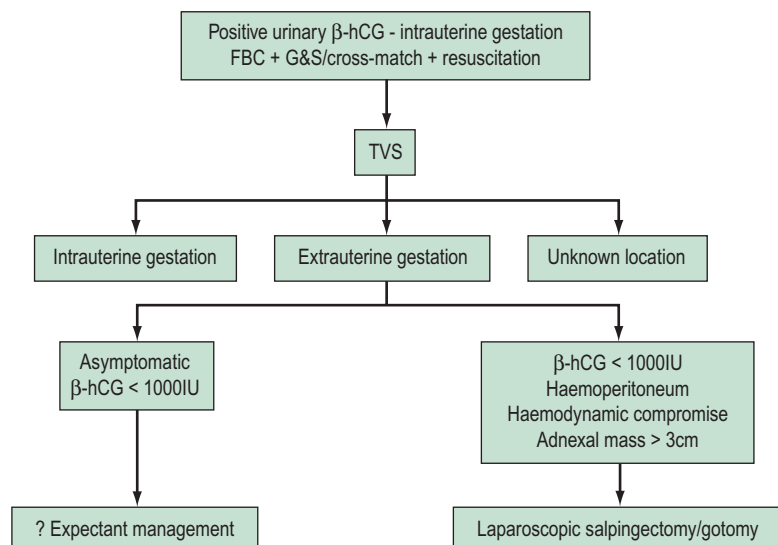

Figure 6.7 Assessment of an extrauterine pregnancy. β -hCG, β -human chorionic gonadotrophin; FBC, full blood count; TVS, transvaginal sonography; G&S, group and save.

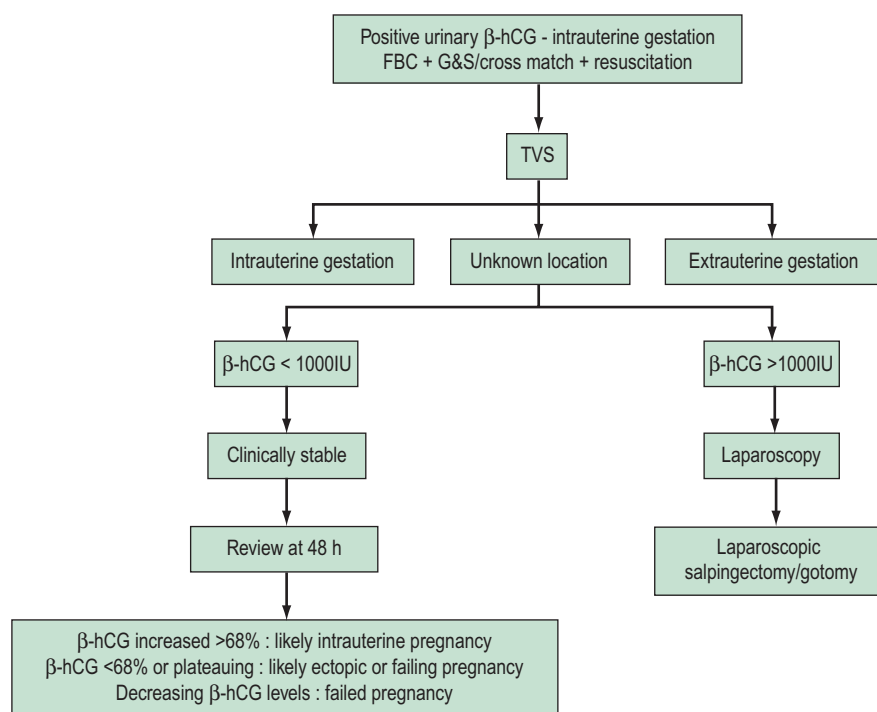

Figure 6.8 Assessment of pregnancy of unknown location. β -hCG, β -human chorionic gonadotrophin; FBC, full blood count; TVS, transvaginal sonography; G&S, group and save.

assessment of the uterine vasculature will aid their diagnosis, prior to arteriography and embolization. If surgical evacuation of retained products of conception is performed in the immediate postnatal period, the recognized higher morbidity associated with the procedure can be reduced by evacuating the uterus under sonographic guidance (Kohlenberg and Casper 1996).

Pelvic pain and a negative pregnancy test

TVUS undoubtedly has a pivotal role in the assessment of early pregnancy complications. Its role in those patients who are not pregnant, however, is more subtle and, rather than

being central to diagnosis, works in parallel with clinical findings and history, serum analyses, urinalysis and other radiological investigations. The role of ultrasound in the patient with acute pelvic pain and the patient with acute vaginal bleeding will be discussed below.

The premenopausal patient

The importance of a complete clinical history and examination cannot be overemphasized, especially with the use of pelvic ultrasound. The premenopausal ovary and endometrium, as visualized with the transvaginal probe, are dynamic structures, exhibiting cyclical changes in mor-

phology and volume throughout the cycle. A knowledge of the normal variations that can be exhibited is important, as the most common ovarian pathology is the functional cyst.

The presence of adnexal pathology in the patient presenting with pelvic pain may be a coincidence, and gentle use of the transvaginal probe to map the pain within the pelvis will help to indicate the structures giving rise to the pain. The overwhelming advantages of the transvaginal approach in the assessment of pelvic pain are not only the excellent diagnostic capabilities, but also that, in the presence of an acute abdomen, especially in women with pelvic inflammatory disease, this route is tolerated much better than a transabdominal approach with a full bladder.

Pelvic pain in association with a pelvic mass

In those patients presenting with pelvic pain in whom there is evidence of a pelvic mass on ultrasound, an assessment needs to be made not only of pain severity and type, but also the nature of the mass. TVUS has a proven track record in experienced hands in the differentiation of uterine myomas from adnexal masses, and also in the characterization of adnexal masses.

The prevalence of adnexal pathology among premenopausal women is high and the overwhelming majority of these lesions will be benign in nature. A large proportion of benign ovarian cysts will be functional and, if symptoms settle, may be managed expectantly.

A careful history and a clear knowledge of the day of the menstrual cycle will prompt the sonographer to the most likely cause of the pain. For example, acute-onset, midcycle pain may be indicative of a follicular or corpus luteal cyst accident. Haemorrhage into a corpus luteal cyst has characteristic sonographic findings (Figure 6.9). The condition tends to be self-limiting and often responds to non-steroidal anti-inflammatory analgesia. Surgery should be avoided if possible.

Although usually self-limiting, the cyclical occurrence of haemorrhagic corpus luteal cyst can be a source of persistent morbidity; if there are no contraindications, use of the combined oral contraceptive to suppress ovulation is beneficial. This is also indicated for women who have clotting factor deficiencies, such as von Willebrand's disease. They may present with an acute abdomen, secondary to a haemoperitoneum, as a result of ovulation or corpus luteal haemorrhage or rupture.

Women with a history suggestive of endometriosis presenting with acute pain may have sonographic evidence of an endometrioma (Figure 6.10). These rarely undergo torsion, as they are often fixed within the pelvis, but may undergo rupture or acute haemorrhage within the cyst. Rarely, they can become infected. Recent cyst rupture may be suggested by the presence of resolving clinical symptoms, with free fluid present in the pouch of Douglas, often with a collapsing irregular cyst wall.

A suggested follow-up regime for women diagnosed with a pelvic mass is shown in Figure 6.11. Intervention will be dictated by the resolution, or not, of the patient's symptoms. If the symptoms resolve and there are no sonographic features of malignancy on the ultrasound, a repeat scan at 6 weeks should be performed to confirm cyst resolution.

Figure 6.9 Haemorrhagic corpus luteal cyst. Fine strands of fibrin are seen within the cyst contents.

Figure 6.10 Large ovarian endometrioma: characteristic 'ground-glass' appearance of the cyst contents.

Ovarian torsion is unusual with adnexal masses <5 cm (Nicholas and Julian 1985). However, there are no pathognomonic features specific to adnexal torsion, and a high degree of clinical suspicion is essential. The clinical history is of acute-onset, constant pain that does not respond to analgesia, often with nausea and vomiting and systemic upset. Of the persistent adnexal masses in premenopausal women, benign cystic teratomas (Figure 6.12) are more likely to undergo torsion than endometriomas. The central feature of ovarian torsion is the cessation of vascular supply. Colour Doppler has therefore been used to interrogate the adnexal mass suspected of undergoing torsion. It is likely, however, that even if flow can be visualized within the mass, despite clinical symptoms and signs of ovarian torsion, ovarian blood flow may still be compromised, as demonstrated by surgically proven ovarian torsion despite the detection of blood flow within the mass (Rasado et al 1992).

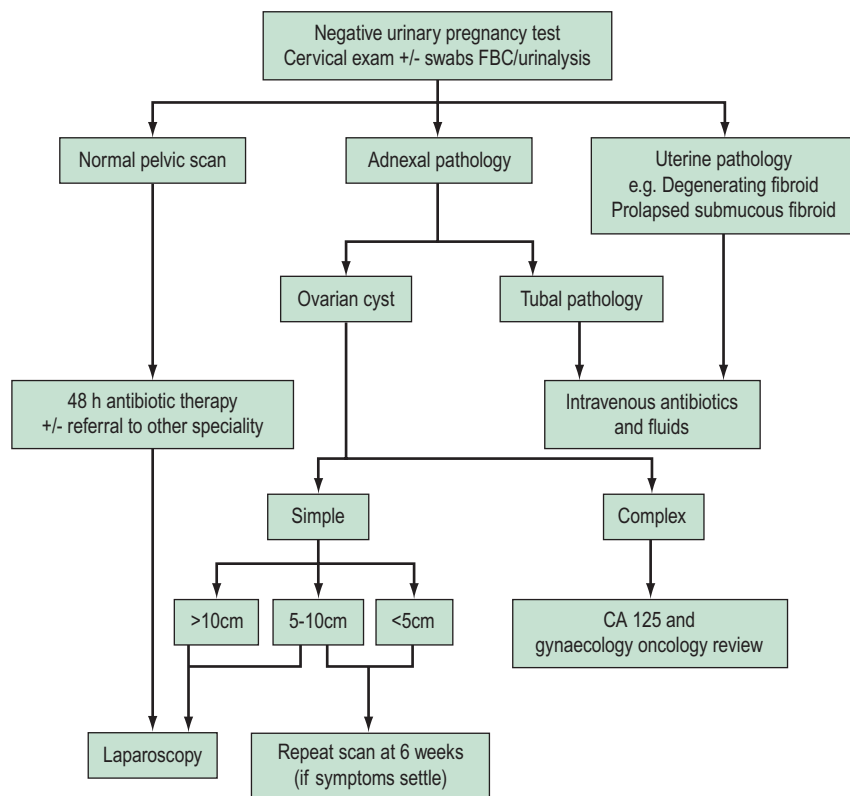

Figure 6.11 Assessment of pelvic mass. FBC, full blood count.

Figure 6.12 Benign cystic teratoma: acoustic shadowing is demonstrated.

Uterine leiomyomas

These may undergo torsion if pedunculated in nature, may prolapse through the cervix or may undergo degeneration, especially during pregnancy. In fibroid degeneration, the patient is often systemically unwell, with pyrexia, leucocytosis and generalized abdominal tenderness.

The ultrasound characteristics of leiomyomas are well documented and cystic areas can be visualized within the fibroid if it is degenerating. Advances in the management of uterine myomas have resulted in a need to provide accurate pretreatment information concerning their size, quantity and location. This is especially true with the increasing use of minimally invasive techniques of fibroid resection. The

ultrasound appearances of myomas are varied. Before the menopause, they tend to be a well-defined heterogeneous or hypoechoic uterine mass. TVUS is used in conjunction with abdominal scanning to ensure that pedunculated subserosal fibroids are not missed.

Tubal pathology

Acute pelvic inflammatory disease, with hydrosalpinx, pyosalpinx or frank tubo-ovarian abscesses, tends to present with systemic upset, leucocytosis, unilateral progressing to bilateral pelvic pain, menstrual disturbances and vaginal discharge. The differentials will therefore include adnexal torsion, acute fibroid degeneration, urinary tract infection and appendicitis.

Acute inflammatory processes within the fallopian tubes tend to produce thick-walled, cystic structures, tender to the touch of the probe (Figure 6.13). However, a chronic hydrosalpinx will have the appearance of a thin-walled structure, not obviously tender on probing and often detected coincidentally (Timor-Tritsch et al 1998).

Acute urinary retention

A full bladder may sometimes be confused with an ovarian cyst. If there is any doubt and the patient is unable to void urine, a catheter should be passed to ensure the bladder is empty. Occasionally, a blood clot may be visible within the bladder.

Pelvic pain with no mass on scan

In the absence of pathology on scan, blood should be taken for leucocytosis and culture. Urinalysis should be performed

Figure 6.13 Tubo-ovarian abscess: an irregular, thick-walled multiloculated structure.

and a complete infection screen, including endocervical and high vaginal swabs. Contact tracing should be performed via the genitourinary clinic. A transvaginal scan may reveal evidence of adhesions and loculated fluid, which may be indicative of previous pelvic or abdominal pathology.

Non-gynaecological pathology

It is often not possible to make a diagnosis based on clinical, ultrasound and serum findings alone. Medical, surgical and urological opinions should be sought where indicated, with early recourse to laparoscopy in those patients who have persistent or worsening symptoms.

The postmenopausal patient

Characterization of any adnexal mass is important within this age group as the risk of a mass being malignant is high (Figure 6.14). Unilocular cysts may be found in up to 20% of asymptomatic postmenopausal women. Numerous studies have shown that simple, unilocular cysts measuring <5 cm in diameter are associated with a very low risk of malignancy (Kroon and Andolf 1995). Blood should be taken for tumour markers and emergency laparotomy should be avoided if at all possible, to allow for adequate oncological work-up of the patient if indicated. Urinary retention must be excluded. Other chronic surgical and medical conditions are more predominant in the older age group, such as diverticulitis, constipation and urinary tract infections. Early recourse to advice from other specialties should be considered in women with pelvic or abdominal pain.

Acute bleeding and a negative pregnancy test

This is most effectively divided into problems occurring in the premenopausal and postmenopausal patient, as the aetiology can be very different. A full history and clinical examination is essential, along with resuscitation of the patient.

The investigation of abnormal uterine bleeding will centre on an assessment of the endometrium (Figure 6.15). Undirected endometrial sampling alone has no role in the evalu-

Figure 6.14 Ovarian endometrioid adenocarcinoma: Stage Ia. Note the large papillary projection from the cyst wall.

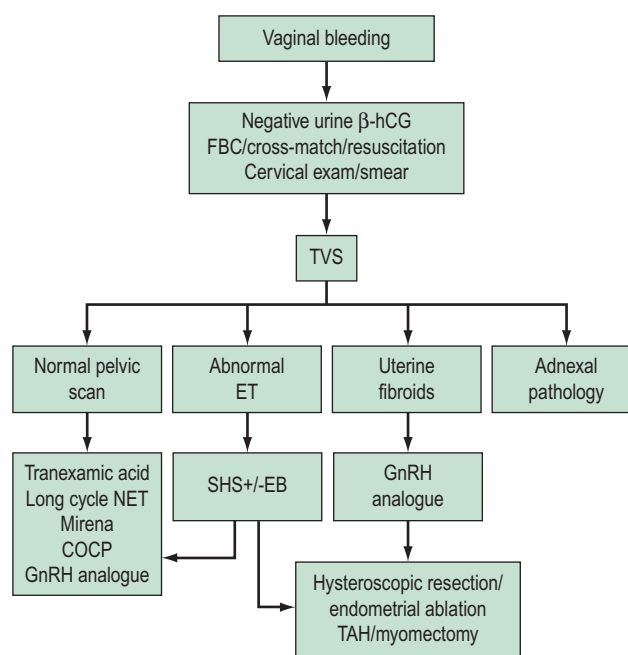

Figure 6.15 Assessment of acute vaginal bleeding. β -hCG, β -human chorionic gonadotrophin; FBC, full blood count; TVS, transvaginal sonography; COCP, combined oral contraceptive pill; GnRH, gonadotrophin-releasing hormone; TAH, total abdominal hysterectomy; NET, norethisterone acetate; EB, endometrial biopsy; ET, endometrial thickening; SHS, Saline Hysteroscopy Study.

ation of abnormal uterine bleeding. It will miss focal lesions, such as polyps and fibroids. Whilst TVUS remains a cost-effective, non-invasive, well-tolerated technique for examining the pelvic organs, it is less specific than hysteroscopy when differentiating between endometrial polyps, myomas, carcinoma and hyperplasia. The addition of a negative contrast medium, such as saline, into the uterine cavity addresses this problem. An overwhelming quantity of data has shown that high-resolution TVUS with saline instillation is as predictive as hysteroscopy in the detection of endometrial pathology.

The premenopausal patient

The main differentials within this group are genital tract disease, systemic disease and iatrogenic causes. When all these have been excluded, a diagnosis of dysfunctional uterine bleeding can be made. History, clinical examination and pelvic ultrasound will help to elucidate the cause. Disease of the genital tract in this age group will focus on benign rather than malignant conditions. Benign pelvic conditions will include fibroids, endometrial and cervical polyps, cervicitis, adenomyosis and endometriosis, along with pelvic infection and foreign bodies. Systemic problems contributing to abnormal uterine bleeding will include coagulation disorders, chronic liver and renal disease, and thyroid dysfunction. Iatrogenic causes will include anticoagulant therapy, intrauterine contraceptive devices and hormonal preparations. There needs to be heightened suspicion of an underlying systemic disease in younger patients presenting with heavy vaginal bleeding, as up to 20% (Kadir et al 1998) may have a coagulopathy. Screening for a coagulopathy is also advised in women with abnormal vaginal bleeding who fail medical or surgical therapy. The endometrial thickness on ultrasound will dictate the need for endometrial sampling, as will the patient's history.

The primary goal with acute uterine bleeding will be to ensure cessation of bleeding, usually with a combination of therapies, such as antifibrinolytics, high-dose progestogens, gonadotrophin-releasing hormone analogues or the Mirena intrauterine system, until definitive management can be effected. Occasionally, urgent examination under anaesthesia with the introduction of a uterine cavity balloon is indicated to stop the bleeding. Interventional radiology with uterine artery embolization may have a role in acute management.

The postmenopausal patient

Abnormal vaginal bleeding in this age group should be attributed to malignancy until proven otherwise. Malignant tumours of the endometrium, cervix, vagina and vulva may all present with vaginal bleeding, as can ovarian tumours, such as granulosa cell tumours. It is wise to confirm that the bleeding is genital tract in origin, as occasionally haematuria and rectal bleeding may present as suspected postmenopausal vaginal bleeding.

Conclusion

The National Service Framework for Children, Young People and Maternity Services (Department of Health 2003) is clear in its aim of providing patient-centred care with the identification and appropriate management of relevant social, medical and psychiatric problems, with a one-stop assessment, diagnosis and management ethos as set out in the NHS Plan (Department of Health 2000). EGU's are excellent examples of how this aspiration can be translated into clinical practice. TVUS plays a pivotal role in assessment of the acute gynaecological patient; as such, it is the core investigating modality in the EGU. It complements a full clinical examination, affording a 'view' of the pelvic structures. Its integration into the gynaecology emergency service facilitates more rapid diagnosis in a number of gynaecological conditions. It also helps to exclude gynaecological pathology, ensuring prompt referral to other specialties and multi-disciplinary teams. Central to its appropriate use will be training and supervision, with up-to-date protocols and regular audit, and awareness of the limitations of personnel and the equipment.

KEY POINTS

1. A normal pelvic scan will not exclude all underlying gynaecological conditions.
2. Visualization of an intrauterine gestation will generally exclude an ectopic pregnancy.
3. Once an ectopic pregnancy has been excluded, early pregnancies should be given the benefit of the doubt.
4. Fetal heart activity should be seen with a crown-rump length of 6 mm or greater.
5. The sonographic appearances of retained products of conception in the immediate postnatal period are variable; management should be based primarily on clinical findings.
6. There are no pathognomonic features specific to adnexal torsion; a high degree of clinical suspicion is paramount.
7. Undirected endometrial sampling alone has no role in the evaluation of abnormal uterine bleeding.
8. Transvaginal saline sonohysterography is as predictive as hysteroscopy in the detection of endometrial pathology.
9. Up to 20% of young women presenting with heavy vaginal bleeding may have a coagulopathy.

Preoperative care

Kate P. Stewart and Saad A. Amer

Chapter Contents			
INTRODUCTION	93	PREOPERATIVE ASSESSMENT	96
CHOOSING THE OPERATION	93	PREOPERATIVE PREPARATION	99
CONSENT	93	KEY POINTS	103

Introduction

Approximately three million operations are performed each year in the UK National Health Service (NHS). Good preoperative care is the key to a successful outcome of these operations. This includes four main aspects: choosing the most appropriate operation, counselling and obtaining consent, preoperative assessment and preoperative preparation. The aim of this care is to optimize the patient's preoperative condition to achieve the best outcome from surgery and to minimize morbidity. Another important objective of preoperative care is to alleviate the patient's fear and anxiety whilst waiting for her surgery. Good preoperative care will also help to avoid delays and cancellations of surgery, thereby maximizing the patient's satisfaction during her journey through the hospital system. Although preoperative care is a patient-centred procedure, it should also involve preparation of the patient's family as well as members of the multidisciplinary teams involved with the care of the patient. Details of the intended operative procedure as well as any social or health concerns should be communicated with the relevant hospital teams.

Choosing the Operation

Choosing the optimum surgical procedure is a crucial first step in the preoperative care of patients. All management options should be carefully considered after full and thorough assessment of the patient's gynaecological as well as other coexisting medical conditions. All treatment options should be explored including no treatment, non-surgical alternatives or more conservative surgery. For example, a patient requesting sterilization should be informed about reversible long-term contraception, and she and her partner should be informed about vasectomy. Likewise, a patient requesting hysterectomy for menorrhagia should be informed of the reversible progestogen-releasing intrauterine system or less invasive endometrial ablation. It is the clinician's duty to make the patient fully aware of all her

options. All the pros and cons and implications of various treatments as well as no treatment should be fully explained to patients. The final decision on the optimum treatment should be mutually agreed between the surgeon and the patient, taking into consideration her wishes and social circumstances (General Medical Council 2008). Quite often, patients do not remember all the information given to them verbally during their consultation. It is therefore important to hand them printed leaflets containing more detailed information on their intended procedure, as well as other relevant treatments. These should also be available in languages other than English depending on the local demographics. With the availability of information on the Internet, patients are very likely to read up on their intended procedures from various unknown Internet sources. Clinicians should therefore direct their patients towards trusted websites offering unbiased information, such as that of the Royal College of Obstetricians and Gynaecologists which provides specific information leaflets for patients.

Consent

Valid consent

It is a legal requirement and an ethical principle to obtain valid consent before starting any treatment or investigation. Although verbal consent is acceptable for most investigations and medical treatments, it is necessary to obtain written and signed consent before any surgical intervention under anaesthesia, with the exception of some emergency situations. For consent to be valid, it must be given voluntarily by an appropriately informed person (either the patient or someone with parental responsibility if the patient is under 16 years of age) who has the capacity to consent to the intervention. The woman must be informed regarding the nature of her condition. Written information should be given, especially as patients are often admitted on the day of surgery and have less time to ask questions. As discussed above, the patient must also be aware of

the alternatives to surgery and the option of no treatment. The Royal College of Obstetricians and Gynaecologists, the General Medical Council and the Department of Health all place importance and have provided guidance on valid consent (Department of Health 2001, General Medical Council 2008, Royal College of Obstetricians and Gynaecologists 2008a).

Consent and operative risks

Patients should be informed of frequent and established serious adverse outcomes related to the procedure. The likelihood of complications associated with the intended surgical procedure should be presented in a fashion comprehensible to the patient. The discussion should include all possible intraoperative risks as well as short- and long-term postoperative complications. Table 7.1 summarizes the risks associated with common gynaecological operations as detailed by the Royal College of Obstetricians and Gynaecologists (2004a–c, 2008a–d).

Consent for additional procedures

It is always good practice to discuss, and include in the consent, any possible additional procedures that may be required during the intended operation. Generally, any additional surgical treatment which has not previously been discussed with the woman should not be performed, even if this means a second operation (Royal College of Obstetricians and Gynaecologists 2008a). One must not exceed the scope of authority given by the woman, except in a life-threatening emergency. There are three different situations where an additional procedure may be necessary during the course of an elective surgery. Firstly, when a minor pathology related to the patient's symptoms is detected such as endometriosis or adhesions in women undergoing laparoscopy for pelvic pain or infertility. In this situation, treatment can be performed if the patient has been made aware of this possibility and has consented for additional minor treatment. The second situation arises when a more complex disease is detected such as a pelvic mass, suspicious looking ovary, severe endometriosis or severe adhesions. Surgery in these situations should be deferred to a second operation after adequate counselling of the patient. In particular, oophorectomy for unexpected disease detected at surgery should not normally be performed without previous consent. The third situation involves intraoperative complications such as injury to the bowel or urinary tract that could lead to serious consequences if left untreated. Corrective surgery must proceed in these cases, and full explanation should be given as soon as practical following surgery.

Who should obtain the consent?

It is the responsibility of the clinician undertaking the surgical procedure to obtain consent. However, if this is not possible, it may be delegated to another doctor who is adequately trained and has sufficient knowledge of the procedure to be performed (General Medical Council 2008). The consent, however, remains the responsibility of the surgeon performing the operation. The clinician obtaining the consent should see the patient on her own first, for at least part of the con-

sultation. She should then be allowed the company of a trusted friend or relative for support if she wishes. If consent is taken on the day of surgery, enough time should be allowed for discussion (Royal College of Obstetricians and Gynaecologists 2008a).

Additional consents

- Fertility treatment using assisted reproduction technology (e.g. oocyte retrieval under general anaesthetic) requires specific consent forms according to the regulations set by the Human Fertilisation and Embryology Authority.
- If images or video records are going to be taken during surgery, consent should be obtained for this and the use specified; for example, for teaching or educational purposes (Royal College of Obstetricians and Gynaecologists 2008a).
- Consent for the presence of medical students during consultations and in the operating theatre as an observer or assistant should be obtained. If the medical student has consent for vaginal examination while the woman is anaesthetized, this should be in writing.
- It is not required to have consent for taking tissue samples unless it is intended for research purposes. Women should be advised that blocks or slides of tissue taken for histological examination might be kept as part of the medical record whilst the rest of the sample is destroyed.

Duration of consent

The consent will remain valid indefinitely unless withdrawn. However, if new information is available between the consent and the procedure (e.g. new evidence of risk or new treatment options), the doctor should inform the patient and reconfirm the consent. It is also wise to refresh the consent form if there is a significant amount of time between consent and the intervention (Department of Health 2001).

Consent of special groups of patients

Jehovah's Witnesses

Jehovah's Witnesses are an Adventist sect of Christianity founded in the USA in the late 19th Century. They believe that accepting a blood transfusion, even autologous blood transfusions in which one's own blood is stored for later transfusion, is a sin. This includes red blood cells, white blood cells, platelets and plasma. Jehovah's Witnesses are aware of the possible risk to life in refusing blood transfusion and they take full responsibility for this. It is important to respect their wishes and to consider alternative measures to blood transfusion. There are special consent forms for Jehovah's Witnesses' refusal of blood products, stating clearly that this may result in the death of the patient. They also specify what blood fractions they might accept (e.g. interferons, interleukins, albumin, clotting factors or erythropoietin) as well as any blood salvage procedures, such as cell saver that recycles and cleans blood from a patient and redirects it to the patient's body. More information can be found on the official website of Jehovah's Witnesses (www.watchtower.org).

Table 7.1 Risks and benefits of common gynaecological procedures

Procedure	Diagnostic hysteroscopy	Diagnostic laparoscopy	Laparoscopic sterilization	Abdominal hysterectomy for menorrhagia	Pelvic floor repair and vaginal hysterectomy for prolapse
Benefit	Identify the cause of symptoms	Identify the cause of symptoms	Permanently prevent pregnancy	Stop menstruation	Improve/resolve prolapse symptoms

*Up to 15% of bowel injuries are not diagnosed at the time of laparoscopy.

[†]Must be discussed prior to surgery.

Adults without capacity

The Mental Capacity Act 2005

Clinicians should work on the assumption that every adult has the capacity to make decisions about her care. The patient should only be regarded as lacking capacity if she is considered unable to comprehend and retain information in order to make a decision after all practical steps to help her do so have been taken without success. A woman is entitled to make a decision based on her own religious beliefs or values as long as she understands what is entailed in her decision, even if it is the clinician's belief that this is not in her best interests. Likewise, a woman should not be thought to lack capacity because she has previously made an unwise decision. The capacity of people with a learning disability, mental illness or apparent inability to communicate should not be underestimated. Capacity may also be temporarily affected by factors such as confusion, pain, fatigue, medication or shock.

Within the English legal system, no one is able to give consent to treatment of adults unable to give consent for themselves. The key principle in care of an incapable adult is that the treatment should be in their best interests. It is lawful to carry out a procedure that is in the best interests of the patient. One cannot sign the consent form on their behalf; rather, one should document in the medical notes why the patient cannot consent for the procedure and why it is in their best interests. This is not confined to the best medical interests; it is to preserve life, health or well-being of the patient. This also covers procedures such as washing and dressing.

It is good practice to involve those close to the patient in order to find out about the patient's values and preferences prior to the loss of capacity. In addition, patients should be encouraged and supported, as far as they are able, to be involved in decisions about their care.

Certain procedures such as sterilization, management of menorrhagia and abortion do occasionally arise in women with severe learning disabilities who lack capacity to consent. They give special concern about the best interests and human rights of the person who lacks capacity. They can be referred to court if there is any doubt that the procedure is the most appropriate therapeutic recourse. The least invasive and reversible option should always be favoured (Department of Health 2001).

Children and young people

People aged 16 years and over are entitled to consent to their own medical treatment using the same criteria for competency as for adults. It is not legally necessary to obtain consent from the person with parental responsibility in addition.

Girls aged less than 16 years must be assessed as 'Gillick competent' to consent for their procedure. This is named after the case of *Gillick vs West Norfolk and Wisbeth AHA* 1986. Mrs Gillick challenged the lawfulness of Department of Health guidance that doctors could provide contraceptive advice and treatment to girls under the age of 16 years without parental consent or knowledge. The House of Lords held that a doctor could give contraceptive advice and treatment to a young person under the age of 16 years if:

- she had sufficient maturity and intelligence to understand the nature and implications of the proposed treatment;
- she could not be persuaded to tell her parents or to allow her doctor to tell them;
- she was very likely to begin or continue having sexual intercourse with or without contraceptive treatment;
- her physical or mental health was likely to suffer unless she received the advice or treatment; and
- the advice or treatment was in the young person's best interests.

This case was specifically about contraceptive advice and treatment, but the case of *Axon vs Secretary of State for Health* (2006) makes it clear that the principles also apply to decisions about treatment and care for sexually transmitted infections and abortion. Thus, if a child is 'Gillick competent' and is able to give voluntary consent after receiving appropriate information, the consent is valid. It is not legally necessary to obtain agreement of an additional person with parental responsibility. It is, however, good practice to encourage them to inform their parents, unless it is clearly not in the child's best interest to do so. It is important to ensure that the consent is voluntary and to be aware of undue influences by parents, carers or sexual partner.

Conversely, if a child assessed as 'Gillick competent' refuses treatment, the person with parental responsibility can over-rule this decision if it is in the best interests of the child. Consideration should be given to applying for a court ruling for this intervention. For parents to be in a position to over-rule a competent child's refusal, they must be provided with sufficient information about the child's condition. This may be in breach of confidence on the part of the doctor treating the child, but may be justifiable in view of the child's best interests. The child should still be as involved as possible in making decisions about their care.

Finally, refusal of treatment by a competent child and persons with parental responsibility for a child can be over-ruled by a court if this is in the best interests of the child (Department of Health 2001).

Preoperative Assessment

The purpose of preoperative assessment is to achieve an accurate diagnosis and to assess the patient's fitness for surgery (risk assessment).

Accurate diagnosis

A thorough clinical examination aided by specific investigations (as necessary) is essential in patients undergoing gynaecological surgery to confirm the diagnosis and to ensure correctness of the planned operation. Special attention should be paid to the extent and complexity of the disease, and the involvement of other organs. For example, patients with complex endometriosis should be assessed for possible involvement of the bowel, bladder or ureter with this disease. Patients undergoing pelvic surgery for stress incontinence should be considered for urodynamic studies if detrusor instability is suspected, if they have had previous surgery for stress incontinence or if they have substantial voiding dysfunction.

Although the diagnosis is usually established during the initial consultations in the outpatient clinic, it is important to reassess the patient closer to or on the day of surgery to detect any changes in her gynaecological condition that may require alteration or even cancellation of the planned surgery. A common example of this is the disappearance of an ovarian cyst prior to ovarian cystectomy. Another example is the enlargement of a leiomyoma to an extent that may necessitate a change in the planned route of surgery. In these cases, a repeat preoperative pelvic ultrasound scan close to the day of surgery should be considered.

Risk assessment

One should start with a thorough assessment of the patient's risk by way of a full medical and surgical history followed by general examination. This will determine which patients require further investigations. Routine preoperative testing of healthy individuals is of little benefit. Guidelines from the National Institute for Health and Clinical Excellence (2003) conclude that no routine laboratory testing or screening is necessary for preoperative evaluation unless there is a relevant clinical indication. Preoperative testing is a substantial drain on NHS resources, and substantial savings can be achieved by eliminating unnecessary investigations (Munro et al 1997). False-positive results may also cause unnecessary anxiety and result in additional investigations causing a delay in surgery. The indications and aims of common preoperative tests are shown in Table 7.2.

Purpose of preoperative risk assessment

- Estimation of physiological reserve (i.e. fitness for surgery).
- Planning perioperative care of patient's care:
 - Day case or inpatient
 - Postoperative recovery bed required in high-dependency unit/intensive care unit.
- Inform doctors and patient of change in risk.
- Opportunistic screening.
- To determine anaesthetic technique.
- To diagnose and correct physiological abnormalities (e.g. anaemia, hypertension, previously undiagnosed arrhythmias).
- To anticipate requirement for crossmatched blood.

Tests should be performed in adequate time to allow for counselling and arrangement of further investigations and/or management as necessary. This should minimize cancellations. Patients should be counselled and their consent obtained before performing all preoperative investigations.

Abnormal findings of preoperative investigations increase with patient's age and American Society of Anesthesiologists' grade. These results may change the management plan of the patient by way of altering, delaying or cancelling surgery. They may also necessitate onward referral to an appropriate speciality or to the anaesthetist. Preoperative correction of abnormalities is important to minimize risk to the patient. For example, anaemia predisposes to intraoperative hypoxia and delayed wound healing. Both anaemia and hypertension cause increased cardiac workload and risk of myocardial infarction.

Assessing patients' suitability for day surgery

Day surgery was devised as a way to increase the capacity of the NHS by the Department of Health in order to meet demands. Patients enjoy it, where appropriate, as a safe, efficient and effective care that provides the least disruption to their lives. Unless the patient requests inpatient treatment or is not found to be suitable, the operation should take place as a day case. The patient's suitability for surgery as a day case will depend on the assessment of their general medical status and fitness for anaesthetic. One should also take account of their home circumstances. Living alone is not a contraindication for day surgery, but they should be encouraged to have a carer to stay with them until they are able to care for themselves. If a patient is not able to go home, they should be assured that they will be cared for overnight.

Gynaecological procedures for day surgery (Department of Health 2002)

- Hysteroscopy (diagnostic and/or therapeutic).
- Transcervical resection of endometrium.
- Laparoscopy (diagnostic and/or therapeutic).
- Termination of pregnancy.

It is also recommended that mixing day-case and inpatient procedures on the same list increases the risk of cancellation of minor cases and hence decreases efficiency.

Assessing patients with allergies

Recognition of patients' allergies to certain medicines or any medical materials such as latex or plaster is of utmost importance. Exposure to such allergens could potentially result in fatal anaphylaxis. Awareness of patients' allergies will also determine theatre location in the case of latex allergy and is important for planning resources. However, it is important to ensure that an allergy is a true allergy rather than a side-effect. For example, a patient may be mistakenly labelled as allergic to penicillin when she has developed diarrhoea or vomiting as a side-effect following penicillin administration. Some allergens, such as penicillin and latex, can be confirmed by specific hypersensitivity tests. However, it can be difficult to confirm or exclude if a patient had a true hypersensitivity reaction to a certain agent. This lack of certainty can be problematic when the patient needs the specific drug or a related drug again and there is no easy substitute. In this case, it may be wise to consult an immunologist before the use of the suspected allergen.

Risk assessment of obese patients

The prevalence of obesity is increasing in the Western world. Obesity is defined as a body mass index (BMI) of more than 30 kg/m² and morbid obesity is defined as a BMI of more than 40 kg/m². Although absolute BMI should not be used as a sole indicator for suitability for surgery or its location, it is the most useful currently available measure of risk. People who are mildly obese pose few additional problems, but those who are morbidly obese have increased health risks associated with surgery. Table 7.3 summarizes common comorbidities in obese patients. They require extra time and early communication before surgery regarding scheduling of surgery, provision for sufficient operative time, resources

Table 7.2 Indications for preoperative tests

Test	Aim	Indication	Further management
Chest X-ray	Assess signs of cardiopulmonary disease	<ul style="list-style-type: none"> Clinical indication (e.g. history of chest disease or recent chest symptoms) Age >75 years Age >60 years with another risk factor (e.g. smoking) 	Assessment by anaesthetist and speciality if appropriate
Electrocardiogram	Identify silent myocardial infarction or arrhythmia	<ul style="list-style-type: none"> Age >60 years Age >40 years if clinical indication 	Correction of arrhythmia
Full blood count	Identify occult anaemia	<ul style="list-style-type: none"> Main factor is extent of planned surgery Age >60 years as may have occult blood loss 	Correction of anaemia. Blood cross-matched. Identify cause of anaemia
Coagulation	Identify clotting abnormality	<ul style="list-style-type: none"> Always require a specific indication such as: <ul style="list-style-type: none"> anticoagulant therapy abnormal liver function tests thrombocytopenia malabsorption cancer surgery 	Liaise with haematology and blood transfusion service
Renal function	Identify renal failure. Avoid acute renal failure following major surgery	<ul style="list-style-type: none"> Age Diabetes mellitus Hypertension Medications (e.g. steroids, diuretics, non-steroidal anti-inflammatory drugs) Renal disease 	Close postoperative monitoring of urine output, change in medication or further renal assessment
Random blood sugar	Identify undiagnosed diabetes	<ul style="list-style-type: none"> No consensus on definite indication Opportunistic screening in those with renal disease 	Fasting blood sugar for diagnosis of diabetes and referral to diabetes service
Urine pregnancy tests	Identify pregnant women – interpreted with last menstrual period. Tests should always be done with the patient's consent	<ul style="list-style-type: none"> All women with a possibility of pregnancy, e.g.: <ul style="list-style-type: none"> irregular menstrual cycles delayed menses uncertain last menstrual period 	In the case of positive pregnancy tests, elective surgery is almost always cancelled due to the risk of fetal injury or loss
Urinalysis	Screen for infection	<ul style="list-style-type: none"> All patients undergoing urogenital procedures and before major surgery 	Treat infection to reduce morbidity
Sickle cell screening	Screen for haemoglobinopathy	<ul style="list-style-type: none"> Women of African, Caribbean, Middle Eastern, Mediterranean or Asian background Family history of sickle gene 	Ideally, test should be done well in advance to allow counselling
Pulmonary function test	Assess respiratory function (expert clinical assessment may be more appropriate)	<ul style="list-style-type: none"> Respiratory disease with ASA >2 and planned major surgery 	

ASA, American Society of Anesthesiologists.

and personnel (Association of Anaesthetists of Great Britain and Ireland 2007).

Preoperative assessment is the key component in assessment and management of risk in the obese patient. All patients should have their height and weight measured and BMI calculated. Special attention should be paid to the patient's exercise tolerance and comorbidities placing obese patients at increased risk such as cardiac, respiratory and metabolic disease. Consideration could also be given to the treatment of sleep apnoea if present. Preoperative assess-

ment should ideally be performed in a multidisciplinary setting with ready access to imaging, laboratory and specialist services to minimize hospital visits. The patient's size in itself may limit the quality of investigations ordered. The quality of electrocardiograms, chest X-rays and trans-thoracic echocardiograms is reduced and patients may not fit in the computed tomography or magnetic resonance imaging machine. Ideally, a consultant anaesthetist with an interest in the management of obese patients should be available.

Table 7.3 Comorbidities in obese patients

Respiratory	<ul style="list-style-type: none"> • Reduced functional residual capacity • Airway closure and desaturation when supine • Difficult intubation due to nuchal fat pad and deposition of fat into soft tissues of neck • Increased acid reflux • Sleep apnoea and obesity hypoventilation syndrome
Cardiac	<ul style="list-style-type: none"> • Hypertension • Hyperlipidaemia • Ischaemic heart disease • Heart failure
Metabolic diseases	<ul style="list-style-type: none"> • Increased incidence of diabetes mellitus • Complications of diabetes mellitus <ul style="list-style-type: none"> • Cardiac and renal disease • Autonomic dysfunction

In order to reduce perioperative risk for obese patients, one should ensure correct case selection by preoperative assessment. This can ensure correct allocation to day-case or inpatient lists, preoperative counselling for smoking cessation and dietary advice, as well as thromboprophylaxis.

An equipment suitable for the morbidly obese patient should be made available. Trolleys, beds and operating tables have a maximum weight-bearing load, usually around 150 kg. Equipment suitable for the morbidly obese patient can carry heavier loads, is wider and can sometimes have a 'tilt-to-standing' mode to reduce manual handling. One should also ensure that large gowns, compression stockings and blood pressure cuffs are available.

Obese patients are at significantly increased risk of venous and pulmonary thromboembolism. All obese patients should be considered for mechanical and pharmacological thromboprophylaxis. With full consideration of assessment and explanation of potential risks, the patient may wish to reconsider whether or not to proceed with surgery or to postpone it until weight reduction has been achieved.

Preoperative Preparation

Thromboprophylaxis

Venous thromboembolism (VTE) kills 25,000 people per year in England. This is more than breast cancer or road traffic accidents. The incidence of deep venous thrombosis (DVT) in gynaecological surgery with no prophylaxis is 16% and the incidence of symptomatic pulmonary embolism (PE) is 1%. VTE usually occurs 1–2 weeks following surgery. DVT is commonly asymptomatic but may result in sudden death from PE or long-term morbidity secondary to venous insufficiency and post-thrombotic syndrome (National Institute for Health and Clinical Excellence 2007).

In order to minimize the risk of VTE in patients undergoing surgery, each patient should be assessed carefully for individual risk factors. Box 7.1 details patient-related risk factors for VTE.

Patients should be given verbal and written information on the risks of VTE and the effectiveness of prophylaxis before surgery. Patients on the combined oral contraceptive

Box 7.1 Patient-related risk factors for VTE

- Age >60 years
- Obesity (BMI >30 kg/m²)
- Personal or family history of VTE
- Pregnancy or puerperium
- Use of oral contraceptives or hormone replacement therapy
- Varicose veins with associated phlebitis
- Thrombophilia including:
 - factor V Leiden
 - prothrombin mutation (G20210A, 5'UTR)
 - deficiencies of protein C, protein S and antithrombin
- Antiphospholipid syndrome
- Severe infection
- Acute medical illness
- Active cancer or cancer treatment
- Active heart or respiratory failure
- Behçet's disease
- Central venous catheter *in situ*
- Continuous travel of more than 3 h approximately 4 weeks before or after surgery
- Immobility (e.g. paralysis or limb in plaster)
- Inflammatory bowel disease (e.g. Crohn's disease or ulcerative colitis)
- Nephrotic syndrome
- Recent myocardial infarction or stroke

pill (COCP) who are undergoing major surgery with subsequent immobilization should be advised to stop the COCP 4 weeks prior to their operation.

Ample hydration and early mobilization

All patients should be given general advice before surgery to help decrease the risk of VTE, including ample hydration and early mobilization. In patients with restricted mobility, leg exercises by physiotherapy should be arranged. Although studies have shown smoking to be a risk factor for VTE in the general population, it does not appear to be so in patients undergoing surgery.

The National Institute for Health and Clinical Excellence (2007) has recommended thromboprophylaxis regimens for gynaecological surgery. Mechanical prophylaxis should be used in all patients with no risk factors for VTE. Pharmacological prophylaxis should be considered in the presence of any risk factors for VTE.

Mechanical prophylaxis

Mechanical prophylaxis includes compression stockings, intermittent pneumatic compression, electrical stimulation and foot impulse devices. There is no difference in the effectiveness of different types of mechanical prophylaxis. They appear to have a similar effect whether used alone or in conjunction with a pharmacological method. All patients should be offered thigh-length graduated compression stockings unless contraindicated (e.g. in peripheral arterial disease and diabetic neuropathy). They should be shown how to wear the stockings correctly and should be monitored and assisted as necessary. The stockings

should be equivalent to Sigel profile (i.e. 18 mmHg at the ankle, 14 mmHg mid calf and 8 mmHg on the upper thigh). Knee stockings may be used instead of thigh-length stocking if there are fit or compliance issues. Patients should be encouraged to wear the stockings from the time of admission until they return to their normal mobility, as immobility is a risk factor for VTE. Intermittent pneumatic compression or foot impulse devices may be used as alternatives or in addition to graduated compression/antiembolism stockings while patients are in hospital.

Pharmacological prophylaxis

Pharmacological prophylaxis should be considered in patients undergoing surgery in the presence of any additional risk factors, as summarized in Box 7.1. Low-molecular-weight heparin (LMWH) should be offered in preference to unfractionated heparin. Fondaparinux can be offered as an alternative, within its licensed indications.

Heparin is composed of a mix of mucopolysaccharides of differing chain length and molecular size, hence the term 'unfractionated heparin'. It produces its major anticoagulant effect by binding to antithrombin (AT) and coagulation enzyme, thereby inactivating thrombin and activated factor X (Xa). For inhibition of thrombin, heparin must bind to both the coagulation enzyme and AT, whereas binding to the enzyme is not required for inhibition of factor Xa. LMWH is derived from heparin by chemical or enzymatic depolymerization to yield fragments approximately one-third the size of heparin. Compared with unfractionated heparin, LMWH has reduced ability to inactivate thrombin, but almost the same ability to inactivate factor Xa. The smaller fragments of LMWH cannot bind simultaneously to AT and coagulation enzyme, hence its inability to inhibit thrombin.

The main advantage of LMWH is its reduced binding to plasma proteins and cells, resulting in a more predictable dose–response relationship, a longer plasma half-life and a lower risk of thrombocytopenia and osteopenia compared with unfractionated heparin. Both decrease the risk of DVT and PE but increase the risk of bleeding.

Fondaparinux is a synthetic pentasaccharide based on the AT binding region of heparin in the body. Hence it is a catalyst for AT inhibition of factor Xa. However, it does not inhibit thrombin directly, because this requires a minimum of 13 additional saccharide units which are present in unfractionated heparin and LMWH. It is therefore a specific, indirect inhibitor of factor Xa through its potentiation of AT. Like LMWH, it is administered subcutaneously on a once-daily dosing regimen. It is more effective than LMWH at reducing the risk of DVT, but has not been shown to reduce the risk of PE and is associated with larger bleeds.

The timing of administering the LMWH should be planned carefully if regional anaesthesia is being employed, with a view to reducing the risk of haematoma formation. Regional anaesthesia should be used where appropriate as this decreases the risk of VTE compared with general anaesthesia. The available evidence is limited regarding whether LMWH can be safely given before surgery or if it should be delayed until after surgery.

Antibiotic prophylaxis

Surgical infections include infections of surgical wounds or tissues involved in the operation, occurring within 30 days of surgery. They prolong hospital stay and are an important outcome measure for surgical procedures. Surgical infections are caused by direct contact from surgical instruments or hands, from air contaminated with bacteria or by the patient's endogenous flora of the operation site. Additional risk factors for surgical site infections are shown in Table 7.4. The most causative organisms are *Staphylococcus aureus*, *Streptococcus pyogenes* and enterococci.

The goal of prophylactic antibiotics is to reduce the total number of bacteria contaminating the operative site and to inhibit their growth. This can be achieved by maintaining adequate tissue levels of antibiotics for the duration of the operation. Reduction of the contaminating bacteria allows the patient's natural defence mechanisms to eradicate the remaining organisms. In addition to prophylactic antibiotics, surgeons should remember that meticulous surgical techniques are also crucial in preventing infections.

The main drawback of using prophylactic antibiotics is increasing the prevalence of antibiotic-resistant bacteria that can predispose to infections such as *Clostridium difficile*. The prevalence of antibiotic resistance is related to the proportion of the population receiving antibiotics and the total antibiotic exposure. Antibiotic prophylaxis use should therefore be restricted to procedures where there is proven benefit.

Prophylactic antibiotics should ideally be given intravenously at anaesthetic induction or no more than 30 min before. This should ensure the maximum blood concentration at the time of skin incision and entry to the genitourinary tract when blood contamination occurs. If given too early, antibiotics could increase the resistance among colonizing organisms. On the other hand, late administration of prophylactic antibiotics will reduce their efficacy, especially if given more than 3 h after the start of the procedure. A single-dose prophylactic antibiotic is effective. Multiple doses may be necessary when surgery is prolonged and where there is a major blood loss of more than 1.5 l requiring

Table 7.4 Risk factors for surgical site infections

Patient related	Operation related
Extremes of age	Length of operation
Poor nutritional state	Skin antisepsis
Obesity	Preoperative skin shaving
Diabetes mellitus	Inadequate sterilization of equipment
Smoking	Poor surgical technique and tissue handling
Coexisting infection	
Bacterial colonization (e.g. methicillin-resistant <i>Staphylococcus aureus</i>)	
Immunosuppression	
Prolonged hospital stay	

ing fluid resuscitation, which results in reduction of the antibiotic concentration. Prolonged use of prophylactic antibiotics for more than 24 h should be avoided as it could result in an increase in resistant organisms (Scottish Intercollegiate Guidelines Network 2008).

A system of classification for operative wounds based on the degree of microbial contamination was developed by the US National Research Council group in 1964 (Berard and Gandon 1964, Culver et al 1991). Four wound classes with an increasing risk of surgical site infection were described: clean, clean-contaminated, contaminated and dirty (Table 7.5). Most gynaecological procedures fall into the 'clean-contaminated' category. Hence, prophylactic antibiotics are highly recommended for certain procedures. However, the final decision rests with the surgeon who should assess the risks and benefits for that patient. There is good research evidence supporting the use of prophylactic antibiotics for vaginal and abdominal hysterectomy with a significant reduction in the incidence of febrile morbidity, pelvic infection and wound infection.

Methicillin-resistant *S. aureus* (MRSA) may be a risk factor for surgical site infection. Those known to be carriers should receive MRSA eradication therapy prior to surgery, and most units now screen patients before surgery.

Urine and respiratory infection

Prophylactic antibiotics are not recommended for the sole prevention of respiratory or urinary tract infections. Although meta-analyses do show a significant reduction in the incidence of urinary tract infection, the results for respiratory tract infection are equivocal. Patients at higher risk of a urinary tract infection (e.g. elderly women and those with indwelling catheters) are more likely to develop bacterial resistance and *C. difficile* due to prophylactic antibiotics (Scottish Intercollegiate Guidelines Network 2008).

Antibiotic prophylaxis against infective endocarditis

Infective endocarditis is a rare condition affecting less than one in 10,000 cases, but with significant morbidity and mortality of up to 20% (National Institute for Health and Clinical Excellence 2008). It is inflammation of the myocardium, which occurs following bacteraemia in a patient with a pre-

disposing cardiac condition. Pathogens are likely to be commensal organisms, the most common being *Streptococcus viridans*, *S. aureus* and enterococci (Gould et al 2006). Up to 75% of cases of infective endocarditis occur without a preceding interventional or dental procedure to account for bacteraemia. Furthermore, there is no consistent association between having an interventional procedure and infective endocarditis. Antibiotic prophylaxis has been shown to reduce the incidence of bacteraemia following an interventional procedure, but does not eliminate it (Bhattacharya et al 1995). The clinical effectiveness of prophylactic antibiotics remains to be proven.

There is not enough evidence in the literature to show an increased risk of infective endocarditis in women undergoing genitourinary procedures. The large number of gynaecological procedures undertaken would mean that the risks of antibiotic prophylaxis against infective endocarditis (e.g. anaphylaxis and bacterial resistance) might outweigh the benefit. The British Society for Antimicrobial Chemotherapy states that there are no good epidemiological data on the impact of bacteraemia from non-dental procedures on the risk of developing infective endocarditis (Gould et al 2006). Likewise, the current guidelines of the National Institute for Health and Clinical Excellence (2008) suggest that antibiotic prophylaxis is not recommended for people undergoing genitourinary tract procedures.

Weight loss

As discussed above, obesity is a major risk factor and is associated with an increase in the incidence of most surgical complications in gynaecological patients. In addition, obesity increases the technical difficulty and prolongs surgery. Obese women should therefore be strongly encouraged to reduce their weight before their planned surgery. However, preoperative weight loss must be controlled and preferably supervised as obese patients often have poor nutritional status, despite their excess weight. A very low calorie diet can be dangerous and may cause cardiac arrhythmias or even sudden death. Women who have undergone bariatric surgery could develop malabsorption. A supervised exercise programme may be best to help with weight loss, exercise tolerance and glucose tolerance (Association of Anaesthetists of Great Britain and Ireland 2007).

Table 7.5 Wound classification and risk of infection

Classification	Description	Infective risk
Clean	<ul style="list-style-type: none"> Uninfected operative wound No acute inflammation No entry to genitourinary, alimentary or respiratory tracts No break in aseptic technique 	<2%
Clean-contaminated	<ul style="list-style-type: none"> Opening to genitourinary, alimentary or respiratory tracts but no significant spillage of contents No evidence of infection or major break in aseptic technique 	<10%
Contaminated	<ul style="list-style-type: none"> Opening to internal organs with inflammation or spillage of contents Major break in aseptic technique 	15–20%
Dirty	<ul style="list-style-type: none"> Purulent inflammation present Intraperitoneal abscess formation or visceral perforation 	40%

Smoking cessation

Smokers have a substantially increased risk of intra- and postoperative complications. They are three to six times more likely to have intraoperative pulmonary complications and postoperative wound infections. Preoperative assessment is a good opportunity to offer smoking cessation intervention, as the patient may be more motivated. This approach has been shown to be effective in reducing preoperative smoking. However, whether or not smoking cessation of such short duration would lead to decreased operative complication rates remains to be determined (Møller and Villebro 2005).

Bowel preparation

Bowel preparation may be considered before gynaecological operations in patients with complex pelvic diseases involving the bowel, such as severe endometriosis, extensive adhesions or malignancy. In such cases, bowel preparation may be necessary if bowel surgery is anticipated or to provide better access for the surgeon. However, a large randomized trial investigating the value of preoperative bowel preparation in patients undergoing bowel resection and anastomosis showed no significant difference in the rate of anastomosis breakdown in women who received mechanical bowel preparation compared with those who did not (Contant et al 2007). However, patients experiencing anastomotic breakdown were less likely to develop an abscess if they had bowel preparation.

Bowel preparation has not been shown to improve the view of the operating field during laparoscopy. Furthermore, it may add to the patient's inconvenience and discomfort during her preoperative hospital stay (Muzzi et al 2006, Lijoi et al 2009).

Additional medications prior to gynaecological surgery

Gonadotrophin-releasing hormone analogues

Gonadotrophin-releasing hormone (GnRH) analogues can be used before fibroid surgery and endometrial ablation. GnRH analogues taken for 3–4 months prior to fibroid surgery (myomectomy or hysterectomy) have been shown to decrease uterine and fibroid size, and to improve menorrhagia after surgery; and to reduce intraoperative blood loss, thereby improving pre- and postoperative haemoglobin levels. In reducing the fibroid size, GnRH analogues can also decrease the rate of vertical abdominal incisions, and reduce the operating time and hospital stay. However, these benefits of GnRH analogues should be balanced against their associated side-effects such as menopausal symptoms (Lethaby et al 2002).

GnRH analogues may also be of value in women undergoing endometrial ablation or resection to help thin out the endometrium. An alternative approach is to perform the procedure shortly after cessation of menstruation when the endometrium is at its thinnest. GnRH analogues are associated with shorter surgery time and increased rate of postoperative amenorrhoea with endometrial resection. However, this benefit does not seem to last in the long term

and does not extend to second-generation ablation treatments (Sowter et al 2002)

Misoprostol

Misoprostol is the most commonly used cervical priming agent worldwide. The most common use is in first-trimester abortion or for surgical management of miscarriage. It is effective in cervical softening and dilatation before surgery. However, there is not enough evidence to conclude that misoprostol is necessary to reduce complications such as cervical laceration. An alternative is Laminaria, although this requires administration to the endocervix via a speculum. Misoprostol can be administered vaginally and sublingually with similar effect, although the sublingual route has more side-effects. It can also be given orally but needs to be administered up to 12 h before surgery (Allen and Goldberg 2007).

Pre-existing medications

Anticoagulants

Patients already on prophylactic anticoagulants due to a previous VTE should stop treatment 5 days before surgery. Heparin and oral anticoagulants should be restarted soon after surgery. If possible, surgery should be postponed beyond 3 months of the previous event. If surgery cannot be delayed, oral agents should be converted to intravenous heparin and should continue following surgery until oral agents can be restarted. Vena caval filters should be considered if the patient has had a VTE within the past month and anticoagulation is contraindicated.

Hypoglycaemic agents

Patients whose diabetes is controlled by diet alone do not usually need any special preoperative measures, providing that dietary control is adequate.

Patients on oral hypoglycaemic agents should discontinue their medication on the day of surgery. Blood glucose should be monitored and, if the levels increase above 13 mmol/l, small doses of soluble insulin could be given. After surgery, metformin therapy should be temporarily suspended (except in minor procedures not associated with restricted intake of food and fluids) until the patient's oral intake has resumed. This is important to reduce the risk of lactic acidosis.

Patients undergoing major surgery requiring prolonged postoperative fasting should be put on an approved protocol of intravenous insulin and glucose infusion before surgery. The dose is determined by regular blood glucose testing. Following surgery, patients can resume their regular treatment when they have resumed their oral intake.

One should utilize the expertise of the multidisciplinary diabetes team and the experience of the patient herself in maintaining tight glucose control.

Oral contraception

Hormonal methods of contraception are used in 29% of women of reproductive age in the UK, with 18% using the COCP. The background risk of VTE is five per 100,000 women per year. This is increased by a factor of three in users of second-generation COCPs (containing levonorgestrel or

Table 7.6 World Health Organization eligibility criteria for contraceptive use in surgery

Contraceptive	Type of surgery	Recommendation
Combined oral contraceptive pill	Minor surgery Major surgery without immobilization Major surgery with prolonged immobilization	Unrestricted use Benefits outweighs risk Unacceptable risk
Progestogen-only pill	All surgery	Benefits outweigh risk

norethisterone) and by a factor of five in users of third-generation COCPs (containing desogestrel or gestodene). The absolute risk remains low with an incidence of 15–25 VTE per 100,000. This risk is increased in the first 4 months of use and falls to levels of non-users within 3 months. There is no evidence that progestogen-only pills increase the risk of VTE.

The Royal College of Obstetricians and Gynaecologists advises that the COCP should ideally be discontinued at

least 4 weeks prior to major surgery where immobilization is expected. Discontinuation of the COCP has been shown to reduce the postoperative VTE rate from 1% to 0.5%. This small absolute risk reduction must be balanced against the risks of discontinuing an effective contraception with the risk of unplanned pregnancy (Royal College of Obstetricians and Gynaecologists 2004a). Table 7.6 shows the World Health Organization's recommendations for contraceptive use in surgery.

KEY POINTS

1. The most appropriate treatment option must be chosen for each patient.
2. The most appropriate treatment location must be chosen for each patient.
3. Preoperative risk assessment is essential to minimize morbidity and make theatre lists as efficient as possible.
4. Consent must always be obtained from a fully informed person with capacity to make a voluntary decision about their care.
5. Children must be 'Gillick competent' to consent to treatment.
6. Obesity is a major risk factor and requires more input before and after surgery.
7. VTE must be taken seriously and compression stockings should be used for all surgical patients. LMWH should be used if there are any additional risk factors.
8. Complete preoperative care requires a team approach with input from the surgical team, anaesthetist and the patient themselves to achieve the best outcome.

Introduction

In major surgery, occasional damage to vital structures is unavoidable, but with good training, appropriate experience and careful application, such damage should be rare. Timely recognition of potential problems has a major impact on the long-term outcome for patients. The request for appropriate assistance from a more experienced colleague, either within the specialty or from another specialty, and early repair, preferably during the original operation, can make the difference between complete and rapid recovery and long-term morbidity and further surgery.

To minimize complications, a surgical technique should be developed that involves careful and accurate identification of tissue planes, preferably with sharp dissection, with the aim of causing the minimum of damage to tissues and structures that are to be preserved. A gentle approach should be used and tissues handled in such a way as to maintain optimum viability.

One should operate under direct vision at all times. The temptation to push an instrument deep into a plane of dissection should be avoided, since inadvertent damage may be caused and bleeding down a deep hole is more difficult to control. Sufficient time should be allowed for each operation, and surgery should not be hurried. Particularly when in training, greater speed will develop by a methodical attention to detail of technique rather than by hurrying individual cases, and outcome is always more important than operative time.

Every case undertaken should be seen as an opportunity to improve technique. Straightforward cases are particularly useful for the practice of sharp dissection to the correct tissue planes. When tissue planes are more difficult to identify, this practice will be invaluable.

One should aim to keep the operation under control at all times; it is much better to spend a little time controlling bleeding, so that the operation can proceed unhurriedly and with good visibility, than to rush on hoping to stop the bleeding as the operation progresses.

This chapter will discuss the common intraoperative complications, and the aspects of technique that reduce the likelihood of these complications occurring. The chapter will also highlight the range of methods used to repair damage, although for the most part, detailed descriptions are not appropriate in a textbook of this type.

The Route

The provisional decision whether to use an abdominal or a vaginal approach for hysterectomy should be made before theatre, but the final assessment of suitability for vaginal hysterectomy is performed under anaesthesia. Each surgeon has personal criteria for attempting vaginal hysterectomy that are based upon training and experience. While some advocate the vaginal removal of large fibroid uteri, most gynaecologists adopt a more cautious approach. Some have also described the removal of normal-sized ovaries, with or without the fallopian tubes, by a vaginal approach, but this requires both special training and instruments. In the event of difficulty, the surgeon should not hesitate to change to an abdominal approach.

Opening and Closing the Abdomen

The layers of the anterior abdominal wall include skin, subcutaneous fat, rectus sheath and oblique abdominal muscles, transversalis fascia and peritoneum. Within these structures

Figure 8.1 Dermatomes.

lie segmental arteries, veins and nerves that supply the dermatomes and myotomes, and also the epigastric vessels (Figure 8.1). Abdominal incisions have been developed that preserve function as well as possible and which heal rapidly with good strength. Commonly used incisions are shown in Figure 8.2.

It should not be forgotten that inappropriate wound closure technique can increase the risk of pulmonary complications and death (Niggebrugge et al 1999). While some surgeons prefer to use electrocautery rather than a cold scalpel to open the wound, there seems to be no difference in the early or late complications in midline incisions (Franchi et al 2001).

Incisions

The vertical midline incision avoids all major nerves, vessels and muscles by dividing the rectus sheath. It gives good access to the whole of the abdomen except the subdiaphragmatic areas, and is a very fast incision to make. Its principal drawback is that it heals slowly and suffers from a high incidence of wound dehiscence and incisional hernia. The development of improved sutures and technique has dramatically reduced these complications. A midline incision should always be closed using the 'mass closure' technique. This involves 1-cm-deep bites of the rectus muscle and peritoneum in a continuous closure, with sutures placed 1 cm apart. The suture material used does not affect the rates of dehiscence or infection, but incisional hernia is more common if braided absorbable material is used (Rucinski et al 2001). The same meta-analysis showed that incision pain and suture sinus formation are more common after non-absorbable material is inserted. Absorbable monofilament used in a continuous mass closure gave the best results.

The paramedian incision is only included for historical interest. The layered closure that was used improved strength when catgut sutures were employed, and reduced the incidence of dehiscence. It is inferior to the mass closure tech-

Figure 8.2 Abdominal incisions.

nique described above, and does not provide improved access to either side of the abdomen.

The majority of gynaecological surgery is performed through a transverse incision, usually a Pfannenstiel incision. By dividing each layer in a different direction, the function is well preserved. Even the muscle-cutting variants of the transverse incision heal more rapidly than vertical incisions. The cosmetic result is superior and, if correctly placed, access to the pelvis is good, although access to the pelvic brim is limited. This incision is difficult to extend if improved abdominal access is required.

The Maylard incision involves dividing all layers in the line of the skin incision and also divides the inferior epigastric vessels. The rectus sheath is not separated from the muscle and closure is in layers, leaving the muscle to be drawn together by the sheath. This incision provides improved access to the pelvic side wall when compared with the Pfannenstiel incision, and is useful for oncological surgery. Many centres now use this incision or a Pfannenstiel incision for radical hysterectomy (Orr et al 1995, Scribner et al 2001).

The Cherney incision is similar to the Pfannenstiel incision but the rectus muscles are divided 1 cm from their insertion into the symphysis pubis. The incision is closed in layers, but the muscle is repaired using a continuous suture in the membranous distal portion of the muscle. This incision can also be useful in oncological surgery or, if placed lower, is useful for complex urogynaecological procedures.

The Rutherford-Morrison incision involves dividing all layers in the line of the incision and is particularly useful for approaching ovarian masses in the second half of pregnancy. The incision is closed in layers and heals well.

Drains

Drains are used either therapeutically, to remove pus, infected material and products from an abscess, or to prevent accumulation of blood, pus, urine, lymph, bile or intestinal

secretions. There is little evidence to support the use of prophylactic drains. In abdominal incisions, drains have been used in an attempt to reduce the incidence of haematoma and wound infection. Unfortunately, they tend to introduce organisms into an otherwise clean area and increase the incidence of wound infection (Cruise and Foord 1973). In addition, pelvic drains do not reduce infection following radical pelvic surgery (Orr et al 1987). Careful attention to haemostasis is preferable and drains should be avoided in most closures.

Closure of peritoneum

This practice has been questioned recently. Research in animal models has suggested that closure of the peritoneum increases rather than decreases peritoneal adhesions. Human studies support this finding, showing that closure of the pelvic peritoneum does not reduce the incidence of post-operative adhesions or obstruction (Table 8.1; Tulandi et al 1988). The peritoneum spreads rapidly across any raw areas left after surgery, although devascularized tissue, such as pedicles, are a focus for adhesion formation. Practice still varies with regard to peritoneal closure, although it probably results in increased adhesion formation (Royal College of Obstetricians and Gynaecologists 1998). However, if a suction drain is used in the wound, the peritoneum must be closed to avoid drawing the bowel into the wound.

Ureteric Damage

Ureters are the organs most respected by gynaecologists. They lie close to the genital tract and repair of a damaged ureter is technically demanding, with results that are not always satisfactory. By recognizing when and where the ureters are at greatest risk and by adopting a safe technique, the risk of damage to the ureter should be minimized.

Anatomical relations

The urinary and genital tracts are closely related in embryological development, and their anatomy and physiology, not surprisingly, are intertwined. The ureter develops from a bud on the posterolateral border of the mesonephric duct near the cloaca, which elongates and eventually fuses with the developing kidney. The ventral portion of the cloaca develops into the urethra, bladder and lower portion of the vagina.

The ureters enter the pelvis by crossing the common iliac arteries in the region of their bifurcation. They descend on

the pelvic side wall, medial to the branches of the internal iliac arteries and lateral to the ovarian fossae. From there, they run on the anterior surface of the levator ani muscles lateral to the uterosacral ligaments to pass beneath the uterine arteries, 1–1.5 cm lateral to the cervix and vagina. The ureters then swing medially around the vagina, to enter the bladder 2–3 cm below the anterior vaginal fornix.

The ureter is accompanied by a plexus of freely anastomosing fine vessels running in the loose tissue surrounding it. The blood supply in the upper portion is derived from the renal and ovarian vessels; in the middle third from branches of the aorta, common iliac and internal iliac arteries; and in the lower part from branches of the uterine, vaginal, middle haemorrhoidal and vesical arteries. The ureter may be mobilized extensively provided this plexus of vessels is preserved.

The ureter is at risk during gynaecological surgery in four regions: at the pelvic brim where it can be confused with the infundibulopelvic ligament; lateral to the ovarian fossa where it can be adherent to an ovarian mass; in the ureteric tunnel beneath the uterine artery; and anterior to the vagina where it runs into the bladder.

The ureter at the pelvic brim and ovarian fossa

At the pelvic brim, the infundibulopelvic ligament with the ovarian vessels also crosses the iliac vascular bundle, usually 1–2 cm distal to the bifurcation of the common iliac artery and the ureter (Figure 8.3). At this point, the ureter and the ovarian vessels are running in parallel in a similar plane and may be confused if care is not taken. Occasionally, the ureter may be duplex. Where the ureter runs lateral to the ovary, it will almost inevitably be associated with any inflammatory or malignant mass. Happily, it will lie on the lateral aspect of the mass where it can be identified and dissected free, usually without difficulty, although in patients with endometriosis, the ureter may be fixed in dense fibrosis.

The key to the safe identification of the ureter on the pelvic side wall is to open the peritoneum and dissect in the retro-peritoneal space. This is most easily done by dividing the round ligament between two clips, dividing the peritoneum in a cranial direction 1.5 cm lateral to the ovarian vessels and in a caudal direction down towards the uterovesical fold. The loose areolar tissue then encountered should be separated by blunt dissection with careful diathermy of any small vessels. The ureter will lie on the lateral aspect of the leaf of peritoneum reflected by this manoeuvre. At this stage, the infundibulopelvic ligament can be safely divided with the ureter under direct vision. If the anatomy of the pelvic side wall has been distorted, this technique will almost always allow the ureter to be identified and followed within the pelvis. If an ovarian mass is present, the ureter may be dissected free from the mass in this retroperitoneal plane.

The lower ureter

The third position where the ureter is at risk is in the ureteric tunnel, where the ureter crosses beneath the uterine artery but superior to the cardinal ligament and approximately 1–1.5 cm lateral to the angle of the vagina (Figure 8.4). It is possible to palpate the ureter in this position by gripping the paracervical tissue between one finger in the pouch

Figure 8.4 Relationship of ureter to the uterine artery. This diagram shows the dissection performed for a radical hysterectomy, but illustrates the close relationship between the ureter and the uterine artery.

of Douglas and the thumb placed laterally in front of the uterine pedicle. The ureter, which is felt as a firm cord running across the cardinal ligament, is surprisingly far lateral to the cervix if the bladder has been properly reflected and the anatomy is normal. However, adhesions, fibrosis or inadequate dissection may disrupt these relationships, causing the ureter to remain fixed near the lateral margin of the cervix.

Damage to the ureter in this site is prevented by carefully reflecting the bladder and by not taking a large pedicle that includes both the uterine artery and the paracervical tissue. The author prefers to take the uterine artery relatively high, at the level of the internal os, which allows the parametrium to fall laterally, taking the ureter with it. The ureter can then be palpated again and a second pedicle taken medial to the first, to include the cardinal ligament.

In most cases, damage to the ureter occurs at this site because the pedicle slips or the original ligature is not ade-

quate. This can be avoided by preparing the pedicle carefully before clamping it. Modern clamps, such as Roget's or Zeppelin's parametrial clamps, rarely slip, and ties should be placed accurately. If bleeding does occur, the ureter should be palpated again after replacing the clamp to ensure that it has not been included.

The ureter is occasionally damaged in its course across the anterior surface of the vagina. This may occur when taking a cuff of vagina, during a vaginal hysterectomy or colposuspension. When dissecting the upper vagina, it is important to keep in the correct plane close to the vaginal wall. Stitches placed either vaginally or abdominally in this area must be in tissue that has been accurately identified.

Repairing ureteric damage

If a ureter is damaged, the presence of the contralateral kidney should be checked. If the ureter has not been cut across but merely crushed or ligated in error, and this is recognized on the table, it is acceptable to remove the ligature and insert a stent into the ureter in the hope that a stenosis will not result. If the ureter is divided, repair will be necessary. In the past, gynaecologists have resorted to simply tying off the divided ureter but this is rarely justifiable now.

Repair of the ureter is technically demanding and may lead to long-term complications. It is not appropriate for a gynaecologist without urological training or extensive urological experience to undertake this. In principle, an end-to-end anastomosis can be performed for ureteric damage at the pelvic brim or above. The ureter is mobilized so that the ends can be brought together without tension. They are spatulated and the anastomosis performed using fine interrupted sutures over a Silastic stent (Figure 8.5). This is removed several weeks later. An alternative for damage at this level is to perform a uretero-ureteric anastomosis.

If the damage has occurred at the level of the ureteric tunnel or lower, the safest method of repair is to reimplant

Figure 8.5 Reanastomosis of a divided ureter. A cleanly cut ureter may be reanastomosed by spatulating the ends and repairing it with fine sutures over a suitable splint. The splint is withdrawn from the bladder at a later date.

Reproduced with permission from Blandey J 1986 Operative Urology, 2nd edn. Blackwell Science, Oxford.

the ureter into the bladder. The bladder is opened between stay sutures. A submucosal tunnel is fashioned, taking care to avoid the other ureter. The distal end of the ureter is brought through the tunnel and, after spatulating the end, is sutured to the bladder mucosa. A couple of sutures into the serosal surface anchor the ureter to the outer layer of the bladder (Figure 8.6).

When damage has occurred higher on the pelvic side wall, the bladder can be elevated to the cut end of the ureter to allow reimplantation without tension, using either a psoas hitch or a Boari flap. In the former, an appropriate part of the bladder is elevated towards the end of the ureter. To facilitate this, the cystotomy is performed across the direction of elevation and is closed in the opposite direction to elongate the bladder. In addition, the contralateral superior vesical pedicle may be divided. The ureter is reimplanted as described previously and the bladder is fixed to the psoas muscle to relieve any tension. This technique will allow a ureter divided at any level in the pelvis up to the pelvic brim to be safely reimplanted (Figure 8.7).

The Boari flap is an alternative to the psoas hitch. A flap of bladder is elevated, the ureter is reimplanted into this and the flap is closed as a tube (Figure 8.8). This allows good elevation of the bladder at the expense of reduced bladder capacity.

Alternatively, a uretero-ureteric anastomosis to the opposite ureter can be performed. This has the disadvantage that both ureters may be compromised but may be the only method if access to the bladder is difficult.

Bladder Damage

Anatomical relations

The bladder, like the ureters, is intimately related to the genital tract by virtue of its embryological development.

Repair of the bladder, however, is more straightforward and the results are very good. It is an extraperitoneal organ that is located behind the symphysis pubis and rests on the anterior part of the levator diaphragm, the anterior vaginal wall and the cervix. The trigone is at the level of the upper vagina, with the base of the bladder related to the anterior vaginal fornix and cervix. When full, the bladder rises out of the pelvis towards the level of the umbilicus and presents a hazard during abdominal incision. The bladder is also at risk in this position if it is adherent after previous surgery or during caesarean section in labour, when the lower segment of the uterus is lifted out of the pelvis, elevating the bladder with it.

Avoiding damage

The bladder must always be emptied prior to pelvic surgery and the peritoneum should be opened superiorly, away from the bladder, when making a transverse incision. It can be palpated as a thickening in the peritoneum, and if there is any doubt about its position, careful dissection should allow the detrusor muscle to be recognized before the mucosa is opened. Opening the peritoneum by blunt dissection with fingers will not necessarily protect the bladder, as it is possible to dissect bluntly into it. Similarly, the technique of tearing the parietal peritoneum open by 'stretching' the wound once the abdominal cavity has been opened can lead to damage to the top of the bladder, particularly after previous surgery.

An essential part of any hysterectomy is separation of the bladder from the cervix and upper vagina. This plane can be found after division of the uterovesical fold of peritoneum merely by pushing caudally with a swab applied firmly to the anterior surface of the cervix cranial to the bladder. This is very quick but inevitably leaves a few small bleeding points on the back of the bladder that may be difficult to find. In addition, the bladder is occasionally damaged by this manoeuvre, particularly after previous surgery.

An alternative approach is to use a combination of sharp and blunt dissection. After dividing the uterovesical fold of peritoneum, the scissors are held slightly opened to begin separation in this plane by pushing the bladder off the cervix. Small blood vessels can be recognized and diathermied before cutting, to maintain haemostasis at all times. Once the correct plane has been identified in the midline, the dissection is extended laterally to mobilize the ureters and can be continued as far as necessary down the vagina. Although a little more time consuming, this technique is safe and can be used on simple cases to gain experience for more difficult situations.

When performing the operation vaginally, the same plane needs to be defined and dissected. If the plane does not develop easily, it is important to use sharp dissection, as merely pushing on the bladder may tear a hole. A sound in the bladder may help to define the correct plane. Alternatively, a finger over the fundus of the uterus or over the broad ligament to the side, once the pouch of Douglas is opened, can define the uterovesical fold of peritoneum and clarify the correct plane for dissection.

The bladder can also be damaged during closure of the vaginal vault, particularly if it has not been sufficiently

Figure 8.6 Reimplantation of the ureter. (A) After opening the bladder, a submucosal tunnel is made along the lateral posterior wall of the bladder. A thin rubber tube is slipped over the ends of the scissors. (B) The ureter is drawn through the tunnel with the rubber tube. (C) The end of the ureter is spatulated and sutured to the bladder mucosa with fine sutures. An indwelling stent may be left in place, although this is not usually necessary.

Reproduced with permission from Blandey J 1986 Operative Urology, 2nd edn. Blackwell Science, Oxford.

mobilized. Sutures may be placed through the detrusor muscle or even into the bladder itself, although this rarely causes problems (Meeks et al 1997). However, if this is recognized at the time of surgery, such stitches should be removed and the bladder mobilized to allow closure of the vault without including the bladder. If damage to the bladder has occurred, this should be repaired and the bladder drained as discussed below.

Repair of the bladder

Should a hole be made in the bladder, this can be repaired after the dissection of the bladder is complete. A stay stitch is usually placed at either end of the hole, and the incision is repaired in two layers using either chromic catgut or Vicryl. Care should be taken that the ureters are well away from the sutures, and, if there is any doubt, ureteral stents should be

Figure 8.7 The psoas hitch procedure. (A) The bladder is incised in the transverse axis. (B) The bladder is fixed to the psoas minor tendon to relieve tension and the ureter is reimplanted as described. The bladder is closed in the longitudinal axis.

inserted. After repair, the bladder is drained with an indwelling catheter for 7–10 days. Provided the bladder is well mobilized and repaired without tension, an excellent result should be achieved.

Repair of the bladder is less likely to be successful after radical radiotherapy, and a high incidence of fistulae is seen in this situation. An additional blood supply is provided by interposing a flap of omentum.

Bowel Damage

Inadvertent damage to the bowel should be unusual, unless adhesions are present. The occasions when damage is most likely to occur are during opening of the peritoneal cavity or when dissecting dense intra-abdominal adhesions. In addition, the rectum lies close to the uterosacral ligaments and posterior wall of the vagina, and may be at risk during extensive pelvic dissection for cervical or vaginal carcinoma.

When reopening a previous incision, it is preferable to enter the peritoneal cavity away from the previous closure. If that is not possible, great caution should be used when approaching the peritoneum. Very occasionally, the peritoneal cavity is almost obliterated and it may be necessary to dissect extraperitoneally around the adhesions to enter the peritoneal cavity.

When dense intraperitoneal adhesions are encountered, the adhesions can usually be divided safely with care and patience. Occasionally, the bowel is so matted together that resection of a small portion may be necessary. Particular care must be used in a patient who has been treated with radio-

therapy, as the bowel is more friable and often densely adherent.

When dividing the uterosacral ligaments close to the pelvic side wall during a radical hysterectomy, the rectum is at risk of being included in the clamps. The rectovaginal space must be opened widely and the rectum dissected free. Care is necessary when entering this space to avoid direct damage to the rectum.

Repair of bowel

Repair of damaged bowel may involve primary closure of a small hole or may be facilitated by the excision of a portion of unhealthy bowel and reanastomosis (Figure 8.9). Consideration should be given to a defunctioning colostomy proximal to anastomosis of large bowel, particularly if the blood supply to the bowel wall is compromised in any way. Factors that have a bearing on this decision are previous radiotherapy, bowel obstruction, gross infection of the operative field or other medical factors such as diabetes, steroid therapy, malignancy and advanced age. If no adverse factors are present, a colostomy may not be necessary. Small bowel usually heals without the need for defunctioning. If there is any doubt about the safety of a repair, a surgeon who specializes in bowel should be involved to help with the repair.

Vascular Damage

Bleeding may occur at any stage of gynaecological surgery, especially if the anatomy is distorted or small tributaries are

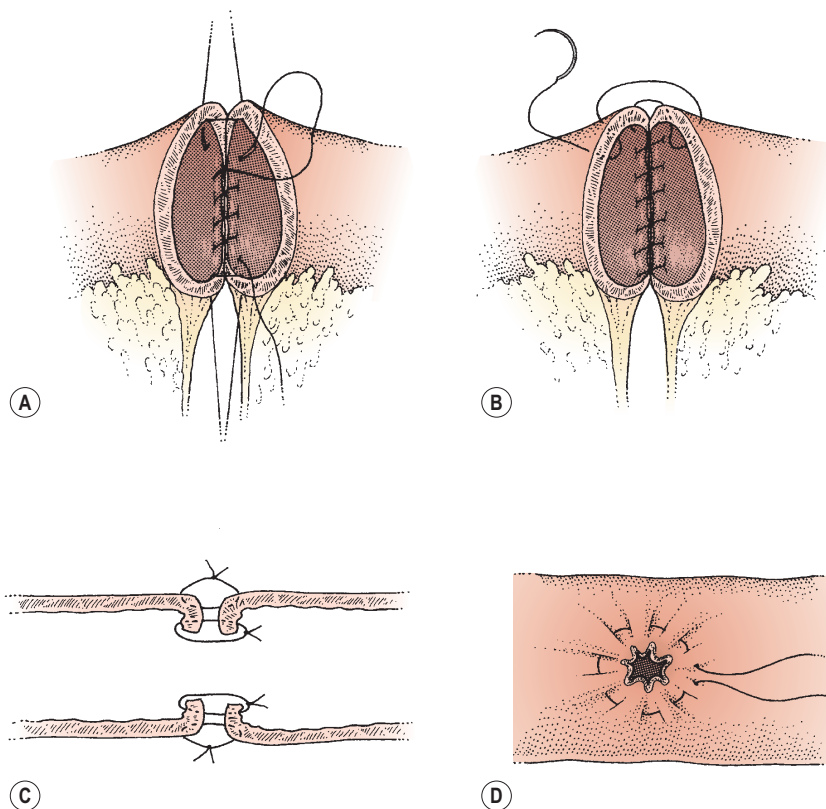

Figure 8.9 Small bowel repair. (A) Suture of small intestine with continuous all-layers suture. (B) Connell inverting suture. (C) Full-thickness sutures reinforced with inverting Lembert suture. (D) Purse-string suture of small intestinal perforation.

increased in size, providing collateral supply to fibroids or tumours. Careful and accurate surgical technique will avoid most, but not all, haemorrhagic complications.

Careful, gentle packing of the bowel out of the pelvis reduces the risk of haemorrhage by maximizing exposure of the operative field. While the bowel must be kept out of the pelvis as much as possible, the packs should not compress the inferior vena cava and obstruct the flow of blood out of the pelvis. Excessively tight packing results in distended pelvic veins and excessive venous bleeding. In the same way, a modest head-down tilt lowers the venous pressure in the pelvis and reduces blood loss.

Bleeding may occur from the main uterine or ovarian vessels while they are being identified, clamped and ligated. Using the technique of pelvic dissection described previously, the ovarian vessels can usually be identified and ligated without difficulty. However, the ovarian vein is particularly delicate and easily torn. A tie around the whole pedicle is preferable to transfixion, as the latter risks haematoma formation proximal to the tie. The proximity of the ureter to these vessels at the pelvic brim is an added problem when endometriosis, inflammatory disease, adhesions or tumours distort the anatomy. In contrast, the uterine artery is divided lateral to the uterus as a plexus of vessels in relatively tough tissue and sutures must be inserted. Care must be taken to include all branches in the ligature. The paracervical tissue and vaginal angle are also rich with arterial tributaries, and similar considerations apply. A figure-of-eight suture in the angle of the vagina is useful to ensure that the heel of the pedicle that contains these vessels does not slip out of the ligature. These pedicles should be adjacent to each other with no space between as haemorrhage can occur later, even if the area looks dry at the completion of the procedure.

Small bleeding points on peritoneum or bladder can be diathermied, but slight oozing from a pedicle signals inaccurate technique and should be corrected by oversewing the pedicle and the adjacent pedicle if necessary. The position of the ureter can be identified by palpation of the cardinal ligament lateral to the pedicle prior to the insertion of further sutures.

If bleeding from these vessels occurs, it will usually be controlled temporarily with pressure while appropriate instruments and ligatures are readied. The swab can then be removed gradually, exposing more of the field bit by bit until the bleeding point is revealed. Suction may be needed to keep the operative field clear. The location of the ureter must be determined by palpation or inspection before attending to the bleeding vessel. It is usually best to stop the bleeding by grasping the vessel gently with fine, long-handled artery forceps. A suture may then be inserted.

Damage to the large iliac vessels usually only occurs during surgery for cancer when lymph nodes or tumour are being removed from the surface of the vessels. However, deeply infiltrating endometriosis may become adherent to the internal iliac vessels, and any retroperitoneal tumour or postoperative adhesions may distort the anatomy so that the iliac vessels are exposed to trauma.

If the blood supply to the leg is compromised by damage to the external or common iliac vessels, serious morbidity can result and it is vital that repair is carried out to the

highest standard. Usually, a vascular surgeon should be involved.

The internal iliac vessels may be safely ligated if damage occurs, but bleeding from the thin-walled veins on the pelvic side wall can be very difficult to control. Initially, bleeding should be controlled by direct pressure, either by a well-placed finger or using a swab. This allows time to assemble the necessary instruments, a fine sucker and fine sutures on small needles to repair the laceration or ligate the vessel, and also a chance to take a deep breath so that the subsequent suturing is not carried out in a panic. Great care should be taken, as rough handling of the vessels can make the situation worse. If in doubt, more experienced help should be obtained.

In most cases, tears in the common and external iliac veins can be repaired by suturing with fine Vicryl. Damage to the arteries is usually less of a problem because the muscular vessel wall constricts and contains the haemorrhage. Local pressure, sometimes supplemented by sutures, usually gives a very satisfactory result. The real danger comes from damage to the internal iliac veins and their branches, or ragged tears removing parts of the wall of the external or common iliac veins. The deeply placed veins retract into the muscle on the pelvic side wall where they become relatively inaccessible. Deeply placed mattress sutures are required to control the haemorrhage. Unfortunately, such sutures may involve one of the large pelvic nerves. This will only become apparent after the operation when the patient wakes up. It may prove impossible to control bleeding from these veins completely. The often-quoted technique of tying off the internal iliac artery in cases of troublesome bleeding is not without its own hazards. The origin of the artery lies over the bifurcation of the common iliac vein, and great care is needed to avoid damaging the internal iliac vein while dissecting behind the artery to pass the ligature. This technique is often less effective than might be hoped in controlling pelvic haemorrhage because such bleeding is often venous. Firm packing may prove to be the only alternative.

More common than either of the two dramatic scenarios above but equally dangerous is a steady ooze from many small venules and arterioles. This usually follows an extensive dissection such as may be required to remove an endometrioma or to mobilize an adherent bladder. This often happens at the end of a long operation during which there has been a slow but steady blood loss that, because it has not been particularly dramatic, has not been replaced fully. A consumptive coagulopathy results as the clotting factors are exhausted. The first step therefore is to hold a hot pack firmly on the bleeding area for 10 min. The second is to commence the prompt replacement of blood and clotting factors. When the pack is removed gently, all may be well or no more than two or three bleeders may persist. These may be controlled with judicious use of diathermy. If there is still significant generalized blood loss not obviously coming from a single significant vessel, a hot pack should be reinserted and kept firmly in place until the blood volume and clotting factors have been replaced adequately. This may take more than 1 h, during which it is often helpful for the surgical team to take a break. If necessary, the abdomen may be closed with the packs in place. Antibiotics are given and the packs removed gently the following day.

Uterine Perforation and False Passage

During dilatation of the cervix, pushing an instrument through the substance of the cervix rather than following the canal may create a false passage. Instruments may also be pushed through the fundus of the uterus into the peritoneal cavity.

When learning to dilate the cervix, one must develop a gentleness of touch that combines pressure with sensitivity or 'feel' for the tissues. It is important to avoid using force with instruments, but rather to feel for the path of least resistance. Due to the barrel-shaped contour of the endocervical canal, an exploring instrument can deviate from the axis of the cervix and not engage the internal os. The size of instrument chosen for this exploration is important, as a fine probe will create its own passage more easily and therefore less pressure should be used. It is said that right-handed people are more likely to perforate towards the right side of the cervical canal, although a false passage can be created in any direction. It then becomes very difficult to identify the true cervical canal and gain access to the uterine cavity.

If a false passage is suspected, one helpful manoeuvre is to perform a bimanual examination with the vulsellum attached and sound still within the passage. It is often possible to feel where the sound is in relation to the axis of the cervix and in which direction the true passage is likely to be found.

When a false passage has been created, provided damage to other organs is not suspected and the patient is not pregnant, the situation can usually be managed conservatively. In most cases, it is best to desist from further attempts at dilatation. In the pregnant patient, however, significant haemorrhage may occur, particularly following lateral perforation into the broad ligament and damage to the uterine vessels. If vaginal bleeding continues or the patient's general condition deteriorates, laparotomy will be necessary. The broad ligament will be full of blood if the uterine vessels have been damaged, and hysterectomy may be necessary to control the blood loss, although ligation of the uterine artery and repair of the perforation may be an option. In some cases, bleeding into the retroperitoneal space may not become apparent for several hours. Careful postoperative observation is necessary to detect this at an early stage.

The consequences of fundal perforation depend on whether the patient is pregnant and what instrument has created the perforation. In a non-pregnant uterus, a dilator through the fundus is very unlikely to cause any problems. It is likely that most perforations go unrecognized by the surgeon. The patient should be observed for a period after recovery but is unlikely to need further intervention. In a pregnant patient, perforation is said to be more likely to cause haemorrhage but, in general, a simple perforation can be managed conservatively. The temptation to 'confirm' the perforation by repeatedly reintroducing instruments into the uterus should be avoided as this may make matters worse.

If there is significant risk of damage to intra-abdominal organs, a laparotomy is indicated because laparoscopy cannot be relied upon to exclude damage to bowel. For example, if a suction catheter has been inserted through a

perforation with suction connected, laparotomy and careful examination of the bowel are mandatory.

Laparoscopy

The incidence of complications in laparoscopic surgery relates very closely to the experience of the surgeon and the training they have received. Gynaecologists have built up extensive experience in the specialty with simple procedures over the last generation. Most senior house officers and junior registrars are trained in diagnostic laparoscopy as one of their earliest procedures. Nevertheless, adoption of the more advanced operative techniques has been slow, and experience in these areas is still very limited. If a high incidence of complications is to be avoided, it is essential that individual surgeons are well trained in the procedures they undertake. General complications of laparoscopy will be discussed but consideration of complications encountered in advanced laparoscopic surgery is outside the scope of this chapter (see Chapter 4, Laparoscopy, for more information).

Damage to bowel

Blind insertion of the Veress needle and first trocar may lead to perforation of intra-abdominal and retroperitoneal structures. Bowel is rarely damaged unless it is adherent to the anterior abdominal wall, but great care must be taken if the patient has had a previous operation or intra-abdominal sepsis. In these cases, the initial trocar may be placed away from the site of the previous incision in an attempt to avoid fixed bowel. Alternatively, the abdomen may be entered using an open minilaparotomy technique and then the incision sealed around a blunt-ended trocar. Difficulty may be encountered in maintaining a good seal using this technique, but specially designed trocars reduce this problem. A new device is available that incises the tissue in front of a blunt-ended trocar 1 mm at a time, and allows visualization of the end of the instrument as it is being inserted. This may prove to be useful in the small number of cases where difficulty is anticipated.

A surgeon experienced in laparoscopic suturing may repair minor damage to the bowel endoscopically. In most cases, it is much safer to perform a laparotomy to allow careful inspection of the whole bowel and open repair of any damage. As it can be difficult to find the hole in the bowel subsequently, it is wise to leave the offending instrument in place until the abdomen is open.

Damage to blood vessels

When inserting the Veress needle and the first trocar, it is vital that these instruments are kept away from the major vessels. The position of the sacral promontory can be palpated and the instruments angled in such a way that they pass below the promontory and into the free space in the midline of the pelvis. While damage to a major blood vessel may be all too obvious, the bleeding may be predominantly retroperitoneal and difficult to see laparoscopically. If the patient's blood pressure has dropped and pulse rate risen sufficiently to suggest the possibility of vascular damage, a laparotomy should be performed

immediately. If the abdomen has to be opened in a hurry, one technique is to lift the laparoscope up to the anterior abdominal wall and cut down on to it, allowing immediate access.

Blood vessels in the abdominal wall may also be damaged. To reduce this risk, the abdominal wall is usually transilluminated to visualize vessels prior to insertion of the secondary trocars. The location of the inferior epigastric vessels should be recognized, as they will bleed profusely and this may be difficult to control. Minor bleeding around a trocar may be controlled either by leaving the trocar in place to tamponade the vessel, or by inserting a Foley catheter through the trocar, inflating the balloon with 30–50 ml of saline and withdrawing the trocar and balloon to apply pressure to the bleeding point. If the vessel requires suturing, this is facilitated by a long J-shaped needle.

Diathermy damage

Problems with laparoscopic use of diathermy stem either from the heat generated at the site of tissue destruction or from current finding an alternative path to earth through an adjacent organ. Tissue coagulated by diathermy becomes very hot and may retain its heat for several minutes. This heat will spread to underlying structures and adjacent organs, and may cause damage. Diathermied tissue must be allowed to cool before coming into contact with adjacent structures. A further problem is the rising impedance in desiccated, diathermied tissue. This may result in the current arcing to a nearby organ that offers a low-resistance path to earth. In a similar way, current may arc to nearby organs if the current is activated before the electrode is in contact with the tissue to be treated.

KEY POINTS

1. Accurate identification of tissue planes and careful dissection will reduce intraoperative complications.
2. The ureter should always be identified on the pelvic side wall before the infundibulopelvic ligament is divided.
3. The ureter should be identified and freed from ovarian masses by opening the retroperitoneal space.
4. If the ureter is damaged, repair should usually be undertaken by a urologist.
5. The bladder may be repaired using two layers of absorbable sutures. One should ensure that the ureters are not included in this repair.
6. Repair of bowel or great vessels, apart from minor damage, should usually be undertaken by a specialist surgeon.
7. Uterine perforation may often be managed conservatively.
8. Repair of laparoscopic damage to bowel will usually require a laparotomy.
9. If laparoscopic damage to major pelvic vessels is suspected, a laparotomy must be performed without delay.
10. Diathermy should only be applied when the electrodes are securely applied to the target tissue, and the target and surrounding tissues are in clear view.

Chapter Contents			
INTRODUCTION	116	KEY POINTS	126
ROUTINE POSTOPERATIVE CARE	116		
RECOGNITION AND MANAGEMENT OF POSTOPERATIVE COMPLICATIONS	120		

Introduction

The postoperative period is the span of time from the end of a surgical procedure until resumption of normal life activity. The duration of this period varies according to the nature of the procedure and the fitness of the patient. It is characterized by restoration of normal physiological functions, healing of tissues from the surgical trauma and a gradual return of physical strength. In the first few hours whilst the patient is recovering from the anaesthetic, she gradually regains her respiratory, cardiovascular and neurological functions, and establishes homeostasis. Recovery of the gastrointestinal tract and mobilization occur in the first 1–3 days after uncomplicated surgery. Healing of tissues and return of full physical strength continue for a variable length of time (1–6 weeks) after discharge from hospital. Although most of the complications from surgery occur in the early postoperative phase, they can still arise after discharge from hospital. Measures should therefore be put in place in collaboration with the general practitioner/primary care doctor and community nurse to support the patient whilst at home and to ensure recognition of any late adverse event.

The last decade has witnessed a dramatic change in the postoperative care of the gynaecological patient. Whilst it was previously routine for women to remain in hospital with bed rest for up to 2 weeks following a hysterectomy, most units nowadays discharge these patients after 3 days. More recently, a growing number of gynaecological units routinely perform laparoscopic hysterectomies as day cases. These changes have been driven by a number of factors, including a realization of the risks associated with prolonged immobilization and hospital stay, such as infective and thromboembolic complications. In addition to these clinical reasons, pressures on hospital beds and funding have driven down length of stay.

Good postoperative care will lead to a smooth and quick recovery from surgery with reduction of complications and

a shorter hospital stay. There are three main objectives of postoperative care:

- supporting the patient during restoration of physiological functions;
- promoting healing of tissues; and
- recognizing and managing complications.

Postoperative care should be tailored to each individual's circumstances with attention to the particular needs of every patient. Standardization of care can be developed, but should be applied with a degree of flexibility to allow the individualization of care.

Postoperative care should be provided by well-trained and skilled nursing staff with input from the surgical team as well as members of a multidisciplinary team including physiotherapists, dieticians, pharmacists and microbiologists. Other specialist postoperative management should be provided as necessary, such as wound care and rehabilitation.

Routine Postoperative Care

Fluid and electrolyte balance

Patients undergoing gynaecological surgery, excluding minor and day-case procedures, require intravenous (IV) fluid administration until oral fluid intake is fully resumed. The daily requirement of fluid should be calculated accurately and the patient should be monitored carefully to ensure adequate hydration. This is important to avoid fluid overload (which could lead to pulmonary oedema) or dehydration (which could result in renal tubular necrosis). When calculating the fluid intake, one should consider the normal fluid requirement (approximately 2.5 l/24 h), intraoperative blood loss and insensible losses (e.g. due to raised temperature). Other factors to be considered when calculating fluid intake include preoperative depletion of fluids, long operative procedures, pyrexia, fluid loss through drains,

excessive vomiting, bowel distension, oral fluid intake, extravascular fluid accumulation (third space) and previous fluid replacement.

Urine output monitoring should be used to determine the status of the intravascular volume and total body water. The normal urine output is 30 ml/h. Patients voiding less than 17 ml/h are oliguric. Other clinical signs of dehydration include mucous membrane dryness, slow skin turgor, tachycardia and raised temperature. Patients should also be monitored for features of fluid overload such as jugular venous distension, mucous membrane turgor, pulmonary rales, third heart sound and pitting oedema. Central venous pressure monitoring should be considered when there is difficulty assessing intravascular volumes. Invasive direct measures of cardiac output that enable accurate measurement of intravascular filling (e.g. measurements of pulmonary wedge pressures and transoesophageal echo) are rarely required after gynaecological surgery.

Oliguria can be prerenal, renal or postrenal. Postoperative oliguria is most commonly prerenal and is caused by insufficient fluid replacement. This can be confirmed by a fluid challenge with the infusion of 250 ml of a colloid such as gelofusin over 15 min. Improvement of urine output after this fluid challenge confirms prerenal oliguria, which can be corrected by increasing the rate of IV fluid administration. If there is no improvement in urine output with the fluid challenge, the patient should be assessed for evidence of pulmonary oedema and renal impairment (due to tubular necrosis). In the elderly or those with known cardiac disease, fluid challenges should be given with caution as this may exacerbate pulmonary oedema.

If prerenal and renal causes of oliguria have been excluded, a postrenal aetiology such as ureteric obstruction should be considered. Diagnosis can be made with renal ultrasound. If this is inconclusive, ureteric catheters can be used for diagnosis and treatment.

The majority of gynaecological patients undergoing surgery are healthy and usually resume their diet within 24–48 h. Postoperative monitoring of electrolytes is therefore not required routinely in these patients. However, electrolyte imbalance may occur under certain circumstances such as persistent vomiting, prolonged IV fluid administration, and after surgery involving extensive tissue damage or excessive drainage from the surgical site. In addition, patients with renal impairment, diabetes or those receiving certain medications (e.g. potassium-sparing diuretics) are at increased risk of electrolyte disturbances. These patients should be monitored for electrolyte imbalance and treated promptly for any abnormality. Both hypo- and hyperkalaemia can result in cardiac arrhythmias and therefore require assessment by electrocardiogram (ECG). Hypokalaemia usually results from delayed oral intake or excessive vomiting. It can be corrected by increasing the potassium content of the IV fluid (20 mEq KCl/l). Hyperkalaemia can occur in patients undergoing extensive surgery due to shift of potassium from traumatized cells into the extracellular space. Moderate or severe hyperkalaemia (potassium level >6 mEq/l) is a medical emergency; if not corrected promptly, it can lead to severe cardiac arrhythmias and death. An input from the medical team should therefore be sought. It can be corrected by IV administration of glucose and insulin to promote potassium shift into the cells. Calcium gluconate is also

given to protect the heart from dysrhythmias. Hyponatraemia is usually secondary to excessive fluid administration or absorption of excessive amounts of irrigating fluid during hysteroscopic surgery, and hypernatraemia is secondary to dehydration.

Bladder care

In women undergoing major gynaecological surgery, a urinary catheter is usually inserted just before the operation to keep the bladder empty throughout the procedure. This helps to minimize the risk of bladder injury and allows good access to the surgical field. Post operatively, the catheter is kept in place during the acute recovery phase for the patient's comfort, to allow monitoring of urine output and to avoid urinary retention due to the general anaesthetic or pain. The catheter should be removed as soon as the patient is able to mobilize and void comfortably. Early removal of the catheter is important as prolonged catheterization may be associated with an increased risk of urinary tract infection (Schjøtz and Tanbo 2006). In patients who sustained a bladder injury during surgery, the catheter should be kept for 7–10 days to allow full healing of the bladder wall, and many gynaecologists would perform a cystogram prior to removing the catheter.

Postoperative voiding difficulty is a common problem in gynaecological surgery, especially following bladder neck operations, and can be due to spasm, oedema or tenderness of paraurethral tissue. It is also common following radical hysterectomy due to extensive perivesical dissection that interferes with the nerve and blood supply to the bladder. Other contributing factors include cystitis and psychogenic factors. Failure to pass urine could also occur as a result of regional anaesthesia (which may cause bladder overdistension and atony) and abdominal pain, which may inhibit the initial voluntary phase of voiding. Following bladder neck surgery, most voiding difficulty resolves within 1 or 2 weeks of surgery, but up to 20% of women can continue with this problem for an extended period (up to 6 months) before being able to void normally (Smith and Cardozo 1997).

If the patient does not pass urine for 4–6 h after catheter removal, residual urine volume should be measured after micturition using a bladder ultrasound scan. This should also be performed in women undergoing bladder neck surgery or radical hysterectomy. Voiding difficulty is diagnosed if the residual volume is consistently greater than 100 ml. If this problem persists after several voiding attempts, a catheter should be inserted for 24 h. The catheter is then removed and further residual volume measurements are carried out. If still high, the patient should be allowed home with an indwelling catheter for 7–10 days. Failing this, the catheter could be left in the bladder for a longer period. Eventually, if voiding difficulty persists, the patient should be trained to perform intermittent self-catheterization.

A suprapubic catheter should be considered during surgery in patients expected to have postoperative voiding difficulty. This allows easier and more accurate measurement of residual volumes. The catheter is clamped and the patient is asked to void urine. This is followed by measurement of residual urine passing through the suprapubic catheter. Another

advantage of this catheter is the reduced risk of urinary tract infections compared with the urethral catheter.

Drains

Although not necessary in the majority of routine gynaecological procedures, drains can be helpful in certain cases. The main indication for placing a drain during gynaecological surgery is surface oozing following extensive pelvic surgery such as adhesiolysis, treatment of extensive endometriosis or complicated hysterectomy. Drainage in these cases is necessary to prevent haematoma formation and to allow early recognition of significant postoperative internal haemorrhage. However, the drain should not be used as a substitute for meticulous intraoperative haemostasis. Other indications for pelvic drainage include pelvic infection (e.g. tubo-ovarian abscess) and clotting disorders, which could result in persistent postoperative oozing.

Intraperitoneal (pelvic) drains have been associated with an increased incidence of infection, and should only be used when the benefits outweigh the risks. Evidence from recent randomized trials and systematic reviews is against the routine use of drains. A recent large randomized trial of drains compared with no drains following radical hysterectomy and pelvic lymph node dissection concluded that drains can be safely omitted in the absence of excessive bleeding during surgery or oozing at the end of surgery (Franchi et al 2007). A systematic review evaluating the value of routine suction drains after retroperitoneal lymphadenectomy in gynaecological tumours concluded that the prophylactic use of continuous suction drains is associated with a significant increase in morbidity and should be avoided (Bacha et al 2009). On the other hand, drainage of surgical wounds (especially clean-contaminated wounds) using a closed-suction system has been used prophylactically to reduce wound infection (Panici et al 2003).

There are two main types of drains: passive (non-suction) and active (suction). Passive drains, which drain by overflow assisted by gravity, are preferred for the peritoneal cavity, where soft tissue can block the fenestrations of suction drains. Passive drains should not be brought out through the incision, to avoid the risk of wound infection. Suction drains are sealed systems with a vacuum to drain a potential space created by surgery such as the subcutaneous or subfascial space. They are also used to drain lymphatic fluid from the groins after lymphadenectomy.

Early removal of drains is recommended to avoid infection and aid mobilization. The precise timing for removal of a drain should be determined on an individual basis and depends on the reasons for its insertion. Drains that were placed prophylactically to avoid the accumulation of blood, pus or lymph can usually be removed when drainage is <100 ml in 24 h, usually by 2 or 3 days after surgery. Drains placed for drainage of an abscess should be managed according to the resolution of the condition.

Postoperative pain management

Effective relief of postoperative pain is of paramount importance as it offers significant psychological and physiological benefits to the recovering patient. Not only does it mean a smooth postoperative course with earlier discharge from

hospital, but it also helps to reduce the incidence of complications (Nagaratnam et al 2007). In addition, there is evidence that good pain relief can reduce the onset of chronic pain syndromes. Inadequate pain management could lead to reduced deep breathing, causing impaired oxygenation. It can also cause inability to cough and clear lung secretions which may lead to lung atelectasis. Pain reduces a patient's mobility, leading to slower recovery and increased risk of morbidities such as deep vein thrombosis (DVT). The benefits of good postoperative pain management are summarized in Table 9.1.

The first step in achieving good pain control is preoperative prediction and accurate postoperative assessment of the degree of pain. Such pain is subjective and can vary greatly in severity between patients from almost no pain to very severe pain. There are two main factors determining the degree of postoperative pain: firstly, the nature, extent and site of the surgery; and secondly, factors related to the patient including fear, anxiety and pain threshold. A previous experience of postoperative pain may also influence the patient's expectation and perception of pain. It is therefore important to plan postoperative pain management through consultation between the surgeon and the anaesthetist based on the predicted pain severity. It is also important to explain to the patient the expected degree of pain and the steps that will be taken to ensure effective pain relief afterwards. It is usually helpful to establish the patient's expectations of pain before surgery. This approach has been shown to minimize the patient's fear and anxiety from pain and to reduce the requirement for postoperative analgesia (Karanikolas and Swarm 2000).

Methods of assessment

After surgery, pain can be assessed using one of several methods such as the visual analogue scale (VAS) or the verbal response score (VRS). With the VAS, the patient chooses a number between 0 and 10 to represent her pain. Zero indicates no pain and 10 means pain as severe as can be imagined. The VRS utilizes a simple five-point scale which either correlates pain severity to words (no pain, mild, moderate, severe, excruciating) or to a number (0–4). The pain should be assessed at regular intervals, preferably charted in graphical form and should form part of the routine postoperative observation.

Table 9.1 Benefits of effective postoperative pain relief

Improved recovery	Patient satisfaction
	Wound healing
	Early mobilization
	Early hospital discharge
Reduced morbidities	Respiratory complications
	Tachycardia and dysrhythmias
	Thromboembolic events
	Acute coronary syndromes
	Chronic pain syndrome

Local anaesthesia = epidural, spinal, peripheral nerve or wound block.
NSAID = nonsteroidal anti-inflammatory drug.

Figure 9.1 The World Federation of Societies of Anaesthesiologists' analgesic ladder. Local anaesthesia indicates epidural, spinal or peripheral nerve or wound block. NSAID, non-steroidal anti-inflammatory drug.

Source: Charlton JE (1997) *The management of postoperative pain. Update in Anesthesia* 7: 2–17 (www.anaesthesiologists.org).

The analgesic ladder

The World Federation of Societies of Anaesthesiologists' analgesic ladder, which has been developed to treat acute pain, can be utilized for postoperative pain (Charlton 1997; Figure 9.1). In women undergoing major gynaecological surgery, the initial pain can be expected to be severe and may need injections of strong opioids [e.g. morphine, preferably by a patient-controlled analgesia (PCA) system], which can be combined with local anaesthesia. As pain decreases with time, analgesia can be stepped down and parenteral opioids can be gradually replaced by the oral route. Strong oral opioids (e.g. oromorph) can be given, to be gradually replaced with a combination of peripherally acting agents (e.g. paracetamol and non-steroidal anti-inflammatory drugs) and weak opioids (e.g. codeine phosphate). The final step is when the pain can be controlled by peripherally acting agents alone.

Opioid analgesia

PCA is an effective way of providing opioid analgesia where the patient titrates the dose to her need by pressing a button that delivers a small bolus (e.g. 1 mg morphine). The PCA system is preset by the anaesthetist to a minimum interval between boluses to prevent overdosage. It is therefore safe and offers high patient satisfaction. Continuous epidural analgesia provides great pain relief for up to 72 h and is more effective than PCA. In addition, it is associated with improved pulmonary function, short convalescence and a lower incidence of morbidities such as pulmonary complications, venous thromboembolism, gastrointestinal side-effects and central venous system depression. It is usually sited by the anaesthetist in theatre and left in for a few days after surgery. Its routine use may be limited by insufficient trained nursing staff to manage it and to treat potential side-effects.

Wound care

Good wound care will promote healing and minimize complications such as infection, haematoma formation or dehiscence. Wound care begins during surgery with careful

handling of tissues, avoidance of cautery for skin incision, meticulous haemostasis, good closure techniques and avoidance of excessive traction on the skin edges (Boesch and Umek 2009). At the end of surgery, a wound dressing is applied, mainly to cover the fresh wound to prevent seepage of serum or blood, but this does not have any protective effect against infection. It should be removed on the first postoperative day when the wound has become dry. Any serous or serosanguinous discharge can be squeezed out by gentle pressure on the wound edges. Patients can be allowed a shower, but should keep the wound dry and clean. Sutures and staples can be removed from transverse wounds after 4–5 days, but vertical wounds usually require 7–10 days to heal.

Wound infection

Wound infection occurs in 3–5% of clean wounds and 10–20% of clean-contaminated wounds in the absence of antibiotic prophylaxis. It usually presents by the fifth postoperative day as erythema, induration and pain in the area surrounding the incision, and may be associated with pyrexia. A wound swab should be taken for culture, and broad-spectrum antibiotics should be given. If the infection progresses to pus formation under the suture line, this should be drained. Usually, at this stage, the wound separates either partially or completely, allowing drainage. However, if the wound remains intact or if the separation is only small, the wound should be opened (in theatre if necessary) to allow drainage. If there is a significant delay in healing with development of devitalized tissue, the wound should be opened in theatre, explored, debrided and packed with gauze, followed by twice-daily dressing changes. At this stage, the tissue viability team and microbiologists should be involved in the care of this chronically infected wound to ensure that the most appropriate dressings and treatments are given. Negative pressure wound therapy may be considered in these wounds to promote the production of granulation tissue and encourage neovascularization (Walsh et al 2009).

Necrotizing fasciitis

Necrotizing fasciitis is a rare but life-threatening and rapidly progressive infection of the superficial fascia and subcutaneous tissues (Addison et al 1984). It often occurs in diabetic and immunosuppressed patients, but can also affect women with other chronic illnesses. It is characterized by dusky and friable subcutaneous tissue with serous drainage from a small wound that may be separate from the original incision wound. It can also occur on the vulva or perineum, often not related to surgery. There is extensive tissue necrosis and a moderate or severe systemic toxic reaction. Very radical excision is essential with antibiotics and supportive therapy.

Postoperative feeding

Traditionally and for many years, postoperative oral intake of fluid and food has been delayed until the recovery of bowel function (return of bowel sounds and passage of flatus) from the temporary postoperative ileus. This was believed to be necessary to avoid vomiting and severe paralytic ileus. However, this practice has not been supported by

good scientific evidence. A recent systematic review of early (<24 h) compared with delayed oral intake after major abdominal gynaecological surgery has provided evidence in favour of early oral intake. The study has shown early postoperative feeding to be safe and associated with a reduced length of hospital stay, but with an increase in the incidence of nausea (Charoenkwan et al 2007). Early feeding was not associated with an increase in complications such as ileus, vomiting or abdominal distension. However, the authors concluded that the timing of postoperative feeding should be individualized according to each patient's circumstances. In patients undergoing benign gynaecological procedures without significant insult to the gastrointestinal tract, early postoperative oral intake should be encouraged. On the other hand, feeding should be delayed in women at high risk of paralytic ileus (e.g. following extensive and prolonged procedures with excessive handling of the bowel).

Mobilization and physiotherapy

The benefits of early postoperative mobilization have been established since the 1940s (Brieger 1983). It reduces the muscle loss associated with inactivity, hastens recovery and reduces the incidence of pulmonary complications. Other benefits include a reduction in the risk of thromboembolic disease and respiratory infection. Mobilization involving an upright position appears to be of greatest benefit in the early postoperative period, with evidence of improvements in pulmonary function (Nielsen et al 2003), prevention of functional decline and possibly a positive effect on depression and anxiety (Brooks-Brunn 1995). Early involvement of skilled physiotherapists is essential to facilitate early mobilization and to deal with the problems arising from prolonged postoperative recovery. In particular, physiotherapists play an important role in the prevention and treatment of respiratory infection.

Recognition and Management of Postoperative Complications

Haemorrhage

Primary haemorrhage occurs in the immediate postoperative period and is usually a result of inadequate intraoperative haemostasis or slipped ligatures due to poor surgical technique. Patients undergoing complex gynaecological procedures such as treatment of endometriosis, division of extensive adhesions or myomectomy are at increased risk of primary postoperative haemorrhage. Secondary haemorrhage is delayed and usually has an infective aetiology. It is more commonly associated with vaginal procedures.

All patients undergoing major gynaecological surgery should be monitored closely for signs of internal haemorrhage in the immediate postoperative period. This can be achieved with regular observations of the pulse, blood pressure, urine output and abdominal distension. It is important to bear in mind that most gynaecological patients who are young and fit compensate very well for hypovolaemia, sustaining a normal blood pressure until late stages when the compensatory mechanisms fail with sudden collapse. It is therefore important, especially in high-risk patients, to

watch for the early signs of hypovolaemia including tachycardia, peripheral vasoconstriction (manifested by cold hands and feet) and signs of anaemia (pallor and low haemoglobin). Although oliguria is another sign of hypovolaemia, it often occurs due to dehydration rather than haemorrhage. In cases of major and rapid haemorrhage, which is beyond the compensatory mechanisms, the patient will experience a rapid fall in blood pressure. In women with intra-abdominal drains, the volume of blood draining could be used as an indication of the severity of blood loss. However, lack of significant drainage does not exclude massive intra-abdominal bleeding, especially when a small drain is used which could get blocked. When there is uncertainty with the diagnosis, an abdominal ultrasound scan, if one is readily available, may aid the diagnosis by confirming intra-abdominal blood collection. The scan can also help in establishing the severity of the condition by estimating the amount of intra-abdominal blood. However, the diagnosis should be primarily based on clinical assessment of the patient.

When internal haemorrhage is suspected, whole blood should be immediately cross-matched and transfused as soon as available. In the mean time, hypovolaemia should be corrected by a colloid or crystalloid intravenous fluid until blood becomes available. The debate over the value of colloid vs crystalloid preparations for volume replacement remains unresolved. A recent Cochrane systematic review by Perel and Roberts (2007) concluded that the continued use of colloids in favour of crystalloids is not supported by evidence from randomized controlled trials and does not improve the outcome of treatment. An urgent full blood count and coagulation screen should be arranged. The coagulation status should be monitored repeatedly during the resuscitation of the patient due to the risk of consumptive coagulopathy. A haematologist should be consulted if there is any abnormality with the clotting system. The next step is for the surgeon to decide whether or not the patient should be taken back to theatre for exploration and achievement of haemostasis. Timing in these cases is critical as any delay in decision could have fatal consequences if the patient enters a state of irreversible shock or disseminated intravascular coagulopathy. On the other hand, rushing the patient back to theatre when conservative management may have been enough will unnecessarily subject the patient to the risks of repeated anaesthetic and surgery. More often, the bleeding is due to generalized ooze, and adequate haemostasis will be difficult to achieve surgically. In some cases, therefore, it may be better to continue the transfusion and correct any coagulation defect rather than to re-explore.

If a decision is made for surgical exploration, the patient should be taken to theatre after initial resuscitation. Patients bleeding vaginally after a hysterectomy could be examined vaginally under anaesthesia. The vault can be reopened and, if a bleeder is identified (usually vaginal branch of uterine artery in one of the angles), it can be secured with a suture. Once haemostasis has been achieved, the vaginal vault can be reclosed and a pack inserted if necessary. In all other cases, a relaparotomy should be performed and all the pedicles should be examined carefully. More recently, laparoscopy has been used successfully for exploration and establishment of haemostasis in patients with postoperative

haemorrhage (Sobolev et al 2005). Intra-abdominal bleeding frequently originates from ovarian vessels. These must be identified clearly and separated from the ureter before the application of diathermy or a ligature. Sometimes, it can be difficult to localize the bleeding point and it may be venous rather than arterial. In these situations, compression with large packs for a few minutes can be effective, or will at least reduce the general ooze, allowing the main bleeding sites to be visualized clearly and dealt with. It is always important to ensure safety of the ureter by palpation or dissection before suturing. If effective haemostasis cannot be achieved, bilateral internal iliac artery ligation or angiographic embolization of bleeding vessels should be considered provided that expertise is available. Failure of haemostasis could be due to coagulopathy, which should be corrected promptly with input from the haematologist. Fresh frozen plasma, which contains all the protein constituents of plasma including the coagulation factors, is used to replace these factors in consumptive coagulopathy. Cryoprecipitate contains a high concentration of fibrinogen that may be required in massive blood transfusion. If haemostasis is impossible, the bleeding site could be compressed with several large packs, followed by closure of the abdomen. The packs should be removed under general anaesthetic after 24–48 h.

Haematoma formation

Vault

Vault haematoma following hysterectomy is relatively common, affecting approximately 20–30% of patients. In most cases, the haematoma is asymptomatic and is only detected on pelvic ultrasound scan. Frequent presentations include lower abdominal pain, low-grade temperature or vaginal discharge. Haematomas are usually self-limiting and will either resolve or discharge via the vaginal vault in the second week following surgery. Infected vault haematomas do not usually contaminate the peritoneal cavity, and generalized peritonitis is rare in these cases. The majority of haematomas can be managed conservatively until they subside. Prophylactic antibiotics can be given to minimize the risk of abscess formation. A large vault haematoma may require drainage, especially if there is evidence of sepsis or if conservative management fails. Drainage is usually performed in theatre under general anaesthetic via a vaginal approach. If interrupted sutures have been used, the removal of one or two may be sufficient to introduce a finger into the gap. Continuous vault sutures will need to be replaced completely when divided to enter the vault. With bimanual compression, the organized clot can be expelled but the blind use of instruments should be avoided. A large bore drain may be required at the end of the procedure to ensure complete drainage.

Wound

Abdominal wound haematomas are also common following open abdominal surgery. They usually cause swelling and bruising around the wound, associated with significant pain. Like the vault haematomas, they are self-limiting and will resolve with time. Management is usually conservative with reassurance of the patient. Large haematomas may require

drainage, especially if there is evidence of infection or if they are associated with severe pain. This is usually carried out in theatre with opening of all or part of the incision. If a subfascial haematoma is suspected, the rectus sheath should also be opened.

Infection and pyrexia

In recent years, hospital-acquired infection has received a great deal of attention from the health authorities. The Department of Health has taken several measures to reduce the transmission of hospital infection, especially against the so-called 'hospital super bugs' (e.g. *meticillin-resistant Staphylococcus aureus* and *Clostridium difficile*). Most hospitals in the UK now have a dedicated infection control team led by a microbiologist who monitors the rates of hospital infections and develops local protocols on the use of antibiotics to minimize bacterial resistance. All hospital staff working in clinical areas receive regular infection control training. The main emphasis of infection control policies is on proper hand hygiene and maintenance of a clean patient environment.

Most major gynaecological procedures (e.g. abdominal and vaginal hysterectomy) fall into the clean-contaminated category (see Chapter 7) and are associated with an infection rate of 10–20% in the absence of antibiotic prophylaxis. In a meta-analysis of 25 randomized controlled trials, involving a total of 3604 women, antibiotic prophylaxis was found to reduce the incidence of infection after total abdominal hysterectomy from 21% to 9% (Mittendorf et al 1993). On the other hand, clean wounds which are performed under complete aseptic conditions are associated with infection rates of 1–5% without prophylaxis. Clean procedures include most adnexal surgeries, laparoscopic procedures and subtotal hysterectomy. Antibiotic prophylaxis does not decrease infection rates following these procedures and should not be given.

Postoperative fever occurring within the first 48 h is not usually caused by an infective process, but may be associated with haematoma formation or pulmonary atelectasis. Later development of pyrexia (after 72 h) is more likely to be infective in origin. The most common site of postoperative infection is the urinary tract (day 3), followed by wound infections (day 5) and collections. Non-infective causes of pyrexia such as DVT should also be considered in the differential diagnosis. Urinary tract infections are not usually associated with urinary symptoms; when suspected, this should be confirmed with urine microscopy and culture. The incidence of urinary tract infection is not changed by the use of prophylactic antibiotics (Brown et al 1988), and is mainly increased with the use of perioperative catheterization. Wound infection usually becomes manifest on the fifth postoperative day (see above). Swinging pyrexia, which persists despite intensive antibiotic therapy, may indicate an infected collection (e.g. pelvic abscess). An ultrasound or computed tomography (CT) scan of the pelvis and abdomen should be performed in these cases to detect any collection. If identified, infected collections not responding to antibiotics may need surgical evacuation. This could be carried out either via a vaginal route (especially after vaginal hysterectomy) or through a laparotomy.

Sepsis is a systemic response to infection which, in severe cases, can lead to septic shock manifested by hypotension and multiple organ failure (Wheeler and Bernard 1999). This requires prompt resuscitation (in an intensive care unit) and aggressive eradication of the source of infection with broad-spectrum antibiotics and surgery if appropriate (Tamussino 2002).

Venous thromboembolism

In the absence of thromboprophylaxis, patients undergoing major (>30 min) general and gynaecological surgery have a significant risk of both asymptomatic (approximately 30%) and symptomatic (approximately 8%) venous thromboembolism (Table 9.2). The risk increases with the number of risk factors (Scottish Intercollegiate Guidelines Network 2002). Women in the high-risk category should be counselled carefully before surgery, and referred to a haematology clinic for risk assessment and advice on perioperative management. The risk factors and thromboprophylaxis have been discussed in Chapter 7.

Diagnosis of deep vein thrombosis

It is always good practice to have a high index of suspicion for DVT following major gynaecological surgery, especially in high-risk patients. The majority of patients with DVT are asymptomatic and could go unrecognized until complicated with life-threatening pulmonary embolism (PE). The calf is the most common site for DVT and usually manifests with swelling, erythema and pain. Examination usually reveals low-grade pyrexia with a swollen, tender and warm calf. Patients with these manifestations should be treated as having DVT until proved otherwise. Diagnosis can be confirmed with Doppler ultrasound on the leg veins. Intravenous venography may be necessary in some cases, but is associated with risk of embolism. Ultrasonography has an average sensitivity and specificity of 97% for proximal DVT. If there is high probability of a DVT but a negative leg Doppler ultrasound, anticoagulation treatment should continue and Doppler studies should be repeated in 1 week.

Diagnosis of pulmonary embolism

Clinically, the 'classic' presentation of PE is an abrupt onset of pleuritic chest pain, shortness of breath and hypoxia.

Table 9.2 Risks of venous thromboembolism following general and gynaecological surgery in the absence of thromboprophylaxis

Type of venous thromboembolism	Risk (%)
Asymptomatic DVT	25
Asymptomatic proximal DVT	7
Symptomatic DVT	6
Symptomatic non-fatal PE	1–2
Fatal PE	0.5

Source: Scottish Intercollegiate Guidelines Network 2002 Prophylaxis of Venous Thromboembolism. SIGN, Edinburgh.
DVT, deep vein thrombosis; PE, pulmonary embolism.

Other less frequent symptoms include haemoptysis and dyspnoea. However, many patients with PE are either completely asymptomatic or have vague and non-specific symptoms such as back pain, shoulder pain, upper abdominal pain, syncope, painful respiration, high fever, productive cough, hiccoughs and wheezing. Therefore, a high level of suspicion should be practised in any postoperative patient presenting with any chest symptoms, especially if no other cause has been found for these symptoms. The main physical signs in patients with PE include tachypnoea, tachycardia, low-grade fever, rales and accentuated second heart sound. Each hospital should develop its protocol for the diagnosis of PE.

Screening for pulmonary embolism

The partial pressure of oxygen (PO₂) in arterial blood should be tested, although this test has little predictive value in patients clinically suspected to have PE. Another screening test is measuring the D-dimer, although it is likely to be raised in the postoperative period. A negative D-dimer in patients with mild-to-moderate clinical suspicion rules out venous thromboembolism. If the result is positive and/or if there is a high probability of PE, diagnostic imaging should be carried out. Other screening tests include ECG and a chest X-ray. The most common ECG findings in PE are tachycardia and non-specific ST-T wave abnormalities. Other findings include S1Q3T3, peaked P waves (p pulmonal), right axis deviation, right bundle-branch block or atrial fibrillation. ECG abnormalities are only present in approximately 20% of cases of PE. ECG is therefore a good positive test in PE (i.e. a positive ECG may be suggestive of PE, but a negative result does not exclude it). Chest X-ray should be performed to exclude other causes for chest symptoms (e.g. pneumothorax, pneumonia). Findings will usually be normal at presentation, although they may rarely show the Westermark sign (i.e. dilatation of the pulmonary vessels proximal to an embolism along with collapse of distal vessels). Over time, chest X-ray may show atelectasis or focal infiltrates, with a picture very similar to infectious pneumonia.

Definitive diagnosis of pulmonary embolism

Definitive diagnosis is by contrast pulmonary angiography. However, due to the invasive nature of this technique, other imaging modalities are more commonly used. Spiral CT scan has recently been shown to be comparable in accuracy to pulmonary angiography, and is now accepted as the preferred primary diagnostic tool. If this is not available, ventilation/perfusion scan (V/Q scan) can be used instead. If V/Q scan shows low probability, bilateral leg Doppler ultrasound studies should be performed. If both are negative with low clinical suspicion, PE can be ruled out. If, however, there is continuing clinical suspicion despite negative V/Q scan and leg Doppler studies, further imaging should be considered such as spiral CT scan, magnetic resonance imaging or angiography.

Treatment of venous thromboembolism

Confirmed or clinically suspected venous thromboembolism awaiting diagnostic confirmation requires immediate

treatment with either low-molecular-weight heparin (LMWH) or unfractionated heparin (UFH). If the diagnosis is confirmed by spiral CT, treatment should continue. If a V/Q scan suggests a high or medium probability of PE, therapeutic anticoagulation should be continued. If the V/Q scan suggests a low probability of PE and ultrasound studies of the legs are positive, therapeutic anticoagulation should be continued. Where the V/Q scan suggests a low probability of PE and ultrasound studies of the legs are negative, anticoagulation can be discontinued if clinical suspicion is low.

LMWHs are the preferred initial treatment of choice. They are more effective than UFH with lower mortality and fewer haemorrhagic complications in the initial treatment of DVT, and are as effective as UFH in the initial management of PE. Systematic reviews have confirmed LMWH as a safe alternative to UFH with the advantage of a fixed-dose regimen reducing the need for monitoring. Long-term use of LMWH is associated with a lower risk of heparin-induced thrombocytopenia, osteoporosis and bone fractures than UFH. However, intravenous UFH remains the preferred treatment in massive PE because of its rapid effect and extensive experience of its use.

LMWH should be commenced and converted to oral anticoagulants once the patient is in the stable postoperative period and the risk of bleeding has reduced. The LMWH should be continued until an international normalized ratio of 2.0–3.0 is achieved. The haematology and anticoagulation clinic should be informed to continue the treatment on discharge and to perform other investigations as necessary.

Life-threatening massive PE requires an immediate multidisciplinary approach involving a senior anaesthetist, haematologist, physician, gynaecologist and intensivist. Cardiopulmonary resuscitation, thrombolytic therapy, percutaneous catheter thrombus fragmentation or surgical embolectomy may be needed in some cases.

Urinary tract injuries

Bladder

Bladder injury is the most common visceral injury in gynaecological surgery. The risk is increased in women with previous surgery, particularly caesarean section and anterior wall myomectomy, where the bladder becomes firmly adherent to the cervix and upper vagina. The damage usually occurs during dissection of the bladder from the cervix, even when applying gentle and blunt methods. The dome of the bladder is the usual site of injury. Intraoperative recognition of the injury is crucial in order to avoid long-term consequences such as fistula formation, which can be difficult to treat. Primary injuries are usually recognized at the time of surgery, although they can easily be missed. In women at high risk of bladder damage, it is usually good practice to exercise a high level of suspicion. Careful inspection of the bladder will usually reveal the injury. If still in doubt, a methylene blue test could be used to check for any bladder tears. A Foley catheter is inserted in the bladder (transurethrally) and methylene blue dye in saline solution is injected through the catheter to fill the bladder. The bladder is then observed as it distends for any leakage of the dye. If a defect is detected, it should be repaired in two layers with absorbable suture material. This can usually be performed by the

gynaecologist. In cases of extensive bladder damage or lacerations, an urologist should be involved with this repair. Following surgery, the bladder should be drained continuously for 10–14 days. It will also be advisable to arrange a cystogram before removal of the catheter to ensure complete healing. An unrepaired bladder injury will result in vesicovaginal fistula, which usually presents in the first postoperative week. Fistulae presenting later may be the end result of a pelvic haematoma or vascular necrosis of the bladder wall.

Ureter

Ureteric damage is less common than bladder injury during gynaecological surgery, with an incidence that varies between 0.5% and 2.5% depending on the underlying pathology. The risk is particularly increased in patients with extensive endometriosis and/or adhesions, which could distort the course of the ureter. The incidence of ureteric damage is also increased in women who received pelvic radiotherapy prior to their surgery. The irradiated tissue is more difficult to dissect and takes longer to heal. The ureteric damage can either occur as a result of direct trauma to the ureter with sharp instruments at the time of surgery, or indirect damage due to delayed avascular necrosis resulting from excessive dissection of the ureter with damage of its blood supply. Delayed ureteric necrosis and damage could also result from thermal injury during the use of electrosurgery. Another form of ureteric damage results from ureteric obstruction due to involvement of the ureter in a suture. Intraoperative recognition of direct ureteric injury can be difficult and requires a significant amount of experience. It is always good practice to suspect ureteric injury in high-risk patients. Careful inspection of the ureter from the pelvic brim downwards will help to detect direct injuries. Common sites of damage are at the angle of the vagina and near the pelvic brim. If in doubt, a ureteric stent should be inserted by the urologist. Repair of ureteric damage should only be undertaken by a urologist. Injury near the brim of the pelvis is managed by end-to-side anastomosis or, more commonly, by end-to-end anastomosis to the opposite ureter. Damage near to the bladder is better repaired with ureteric reimplantation into the bladder using either a psoas hitch or bladder flap. Unrecognized ureteric injury will result in extravasation of urine, which collects in the pelvis causing pelvic discomfort and pyrexia. Urine may also leak from an abdominal or vaginal incision. Ureteric obstruction may cause loin pain and pyrexia in the postoperative period. It may also go completely unrecognized, and be discovered many years later as an incidental finding. Percutaneous nephrostomy may be required if hydronephrosis develops. Cystoscopy and retrograde insertion of ureteric stents is an alternative but often less satisfactory approach.

If a fistula is suspected in the immediate postoperative phase, a urinary catheter should be inserted immediately to assess urine output. A three-swab test will help to identify vesicovaginal fistula, but urine leakage around the catheter may be misleading. Other tests that may help to establish the diagnosis include ingestion of indigo carmine with later vaginal inspection to determine whether a fistula is present. Intravenous urography will help in locating the site of damage, but small fistulae may be difficult to see.

Spontaneous healing of a damaged bladder is dependent upon the extent of the urinary leakage. A small leakage usually heals in approximately 7–10 days and can therefore be managed conservatively. If this fails or if the leakage is more significant, surgical repair of the defect should be undertaken by a urologist.

Bowel complications

Bowel obstruction

Mechanical bowel obstruction caused by adhesions or twisting of a loop of bowel is rare in gynaecological surgery. It usually occurs approximately 1 week after surgery and presents with persistent vomiting and abdominal pain with absence of passage of flatus or faeces. Signs include abdominal distension and tenderness with tinkling bowel sounds. An abdominal X-ray would show dilated loops of bowel. It usually settles within 48–72 h with nasogastric aspiration plus IV fluids. If there is no improvement, contrast imaging should be performed to identify the site of obstruction for surgical correction. The presence of clinical evidence of peritonitis requires immediate surgery.

Paralytic ileus

Abdominal gynaecological surgery is usually followed by a physiological ileus due to manipulation of the bowel. The small bowel typically regains function within hours. The stomach regains activity in 1–2 days and the colon regains activity in 3–5 days (Cameron 2001). Postoperative adynamic ileus or paralytic ileus is defined as gut ileus persisting beyond 3 days following surgery (Livingston and Passaro 1990). Paralytic ileus is uncommon following benign gynaecological procedures as they are not usually associated with significant insult to the bowel.

Paralytic ileus manifests with abdominal distension, nausea and vomiting with delayed passage of flatus or faeces. A distinguishing feature is absent or hypoactive bowel sounds, unlike the high-pitched sound of mechanical obstruction. The abdomen of ileus reveals no discernible peristalsis or succession splash. An abdominal X-ray will reveal dilated loops of bowel.

The majority of patients will improve with conservative management by resting of the bowel, IV fluids and nasogastric tube drainage. Electrolyte imbalance, especially hypocalcaemia, should be corrected. Unresolved cases should be investigated for potentiating factors such as intraperitoneal abscess or retroperitoneal haematoma, which should be drained under radiological control (Gerzof et al 1981).

Bowel injury

Fortunately, inadvertent bowel injury is uncommon during benign gynaecological surgery with an incidence of 0.3–0.8%, with the majority (70%) being minor lacerations (Dicker et al 1982). The small bowel is the site of injury in approximately 75% of cases. Abdominal rather than vaginal or laparoscopic surgery is associated with a higher rate of damage. The incidence of bowel damage during laparoscopic surgery is 0.5% (Garry and Phillips 1995). The site, extent and timing of presentation of bowel injury will determine the presentation, management and outcome. Postop-

erative large bowel leak is a serious and life-threatening complication. Risk factors for bowel injury include adhesions, endometriosis, sepsis, obesity, and previous pelvic or abdominal radiotherapy.

Intraoperative detection of bowel injury

There are three main types of bowel injury: direct trauma with sharp instruments, thermal injury with electrosurgery, and devascularization with subsequent necrosis due to extensive dissection. The former injury results in intraoperative perforation or laceration. This is not always easy to recognize and requires a significant amount of experience. The damage may be detected if it occurs on a visible bowel surface or when there is an obvious leak of bowel contents (e.g. faeces). However, in a significant proportion of patients, neither of these is obvious and the damage can easily be missed. Small bowel contents are not usually easy to notice, which leads to 60% of small bowel injuries being missed (Hill 1994). To minimize the possibility of missing bowel damage, it is important to have a high level of suspicion, especially in difficult or high-risk cases. Consideration should be given to asking a colorectal surgeon to explore the bowel for suspected damage. In patients suspected to have bowel injury during extensive laparoscopic surgery in the cul-de-sac, a 30 cc Foley catheter could be inserted into the rectum. With clamping the bowel above the site of dissection, the pelvis is filled with physiological solution and air injected through the Foley catheter by a 100 cc syringe. The appearance of bubbles in the solution will indicate perforation. Alternatively, a 50% betadine solution could be injected and the bowel observed for trailers of betadine leakage.

Delayed presentation of bowel injury

Indirect bowel injuries cannot be appreciated during surgery and usually present several days later. It is therefore important that patients at high risk should be watched carefully in the first few postoperative days for signs of bowel injury. Patients undergoing day-case surgery present a major concern as they may develop bowel injury at home, which could potentially be fatal if not diagnosed early. It is therefore important to warn all day-case patients about early signs of bowel damage, and advise them to return to the hospital immediately rather than seeking help from their family doctors.

In women who sustain a direct trauma to the bowel that was missed during surgery, symptoms of bowel leak will present 48–72 h later. On the other hand, thermal bowel damage or delayed necrosis due to devascularization may not manifest itself until 6–8 days after surgery.

Minor laceration or Veress needle puncture

Most of these injuries heal without any consequences except if there is an obstruction distal to the injury. This may result in leak from the bowel a few days after surgery.

Large bowel leak

Large bowel leak is a serious and life-threatening complication, especially if there is delay in the diagnosis. The

early symptoms of abdominal pain and distension associated with nausea and vomiting could be mistaken for postoperative symptoms. The diagnosis may not be apparent until septic shock and collapse supervene. Large bowel leak usually presents with generalized peritonitis, giving widespread peritonism and guarding with absent bowel sounds and marked deterioration of the patient's general well-being. In some cases, leaking may be localized with abscess formation, giving rise to swinging temperature which does not respond to antibiotics, vomiting and abdominal distension. Abdominal X-ray reveals gas under the diaphragm or distended loops of small bowel, although plain films are not usually helpful. It is important to ask a colorectal surgeon to review the patient at an early stage if bowel injury is suspected. An early resort to laparotomy and exploration may be crucial to achieve a good outcome.

Small bowel leak

The early symptoms of small bowel leak are less pronounced than those of the large bowel. Abdominal pain and distension associated with vomiting are the main early features. Initially, bowel sounds may still be present with passage of flatus and stool per rectum. With time, symptoms will worsen with localized signs of tenderness and development of a pelvic mass.

Faecal fistula

Rarely, a rectovaginal faecal fistula may develop following a difficult hysterectomy in patients with severe endometriosis with obliteration of the pouch of Douglas. If the large bowel leak is close to the vault, it can discharge through the vault resulting in a fistula. This is usually easily diagnosed with a speculum on vaginal examination, although a small fistula may be difficult to see.

Management of bowel injury

If the damage is recognized during surgery, a bowel surgeon should be summoned to theatre to manage the damage. Depending on the site and extent of the damage, the treatment will either be oversewing the injury, local resection and reanastomosis, or resection with a temporary defunctioning colostomy.

In patients with delayed presentation of bowel injury, laparotomy through a midline incision should be undertaken. If the leak is from the large bowel, diversion proximal to the leak may be required. A small bowel leak may be treated with resection and reanastomosis. Most of these patients are usually generally unwell and should receive postoperative care in an intensive care unit.

A rectovaginal fistula can be treated with resection of the affected bowel segment with closure of the rectal stump and colostomy (Hartmann's procedure). A small rectovaginal

fistula can be managed conservatively with a defunctioning colostomy.

Pulmonary complications

Postoperative pulmonary complications after abdominal surgery include chest infection, atelectasis, pulmonary oedema and pulmonary embolism. Atelectasis is the most common pulmonary complication, and has been estimated to occur in 20% of patients having upper abdominal surgery and 10% of patients having lower abdominal surgery (Bartlett 1980).

Risk factors for postoperative pulmonary complications include smoking, old age, obesity, upper respiratory tract infection, positive cough test (recurrent coughing after deep inspiration and initial cough), perioperative nasogastric tube and long duration of anaesthesia (McAlister et al 2005, Pappachen et al 2006). Arterial blood gas analysis will determine the severity of the problem. Initial treatment is a higher concentration of oxygen supplied via an oxygen mask. Consideration of assisted ventilation should be made in patients unable to maintain saturation >90% or with $PO_2 < 8.0$ kPa with referral to a critical care specialist.

Cardiovascular complications

Any patient receiving a general anaesthetic is at increased risk of developing myocardial ischaemia, especially if there is underlying heart disease. Obtaining a good medical history of cardiac disease is very important in predicting cardiac complications. Elective surgery should be delayed in patients with a history of myocardial infarction within the preceding 6 months (Doshani and Shafi 2003).

Cardiac complications include arrhythmias or myocardial infarction, which can present in the immediate postoperative period. Prolonged arrhythmias may lead to hypotension and exacerbate the effects of hypovolaemia secondary to surgery, resulting in further deterioration of tissue perfusion. Cardiac function may be further compromised by acidosis, hypoxaemia and fluid overload as a consequence of excessive fluid replacement to correct hypovolaemia.

Patients experiencing chest pain after surgery should be investigated for a cardiac cause. It is important to remember that chest pain may be masked by strong postoperative analgesia. Other important signs to raise the possibility of cardiac complications include unexplained tachycardia and hypotension, the presence of a new murmur or evidence of pulmonary oedema. These findings may indicate myocardial infarction and should be investigated with serial cardiac enzymes and ECG. Patients presenting with arrhythmias should be investigated for an underlying cause such as sepsis, hypovolaemia, pyrexia, electrolyte imbalance or drug toxicity. Referral to a cardiologist should be arranged when a cardiac problem is suspected. Thrombolytic therapy is contraindicated within 5 days of surgery.

KEY POINTS

1. Careful preoperative assessment and medical optimization prior to surgery improve postoperative care.
2. Appropriate choice of operation performed by those appropriately trained is the most important factor in minimizing postoperative complications.
3. Whilst most gynaecological procedures do not induce major fluid and electrolyte problems, gynaecologists need to be aware that certain circumstances could lead to electrolyte imbalance such as ileus and persistent vomiting.
4. Be alert to potential hyponatraemia if there are significant deficits of fluid following hysteroscopic procedures.
5. Effective postoperative analgesia using patient-based methods allows early mobilization and reduces respiratory complications.
6. Atelectasis and urinary tract infection are the most common causes of postoperative pyrexia.
7. Pelvic haematomas are common after hysterectomy and may be the cause of postoperative pyrexia or unexpected anaemia.
8. There is a significant risk of DVT after major gynaecological procedures, and each patient must be given appropriate prophylaxis relevant to risk status.
9. The majority of DVTs which precede PE are not recognized clinically, so be vigilant to detect potential DVTs.
10. If postoperative complications occur, it is the responsibility of the operating gynaecologist to liaise with the appropriate specialty and ensure that the patient is investigated and treated promptly.
11. Gynaecology patients are most often young and fit before surgery, and thus may not reveal signs of internal haemorrhage until the late stages and then quickly decompensate.
12. Early recognition of bowel and urinary tract damage reduces the risk of serious morbidity.
13. Damage to bowel and urinary tract should only be repaired by experienced practitioners.
14. Local audit will identify areas of concern in surgical technique and infection control.

REGULATION OF HORMONE SECRETION AND ACTION	129	KEY POINTS	142
HORMONE RECEPTORS	131		

Introduction

The term 'hormone', derived from the Greek word *hormaein* meaning to arouse or excite, was first used in 1905 by Sir Ernest Starling in his Croonian Lecture to the Royal College of Physicians. It is this ability to excite and modulate the behaviour of cells that is the fundamental defining characteristic of hormones.

Hormones are one of the important means by which cells communicate with each other. They ensure that the body's physiological systems are coordinated appropriately, and if this is impaired, as occurs with hormone deficiency or excess, function is compromised. Classically, hormones are synthesized by specialized cells, which may exist as distinct endocrine glands or be located as single cells within other organs, and secreted into the blood stream and transported through the circulation to a distant site of action (endocrine effect). However, autocrine or paracrine actions may also be prevalent and indeed modulate the function of the original endocrine cell type (Figure 10.1).

Hormones: Types and Action

There are three major groups of hormones according to biochemical structure and method of synthesis:

- peptides and proteins;
- amino acid derivatives; and
- steroids.

Peptide hormones

The majority of hormones are peptides and range in size from very small (thyrotrophin-releasing hormone has just three amino acids) to small [thyroid-stimulating hormone

(TSH) has over 200 amino acids]. Some peptide hormones are secreted directly, but most are stored in granules, the release of which becomes a major control mechanism regulated potentially by another hormone as part of a cascade or by innervation.

Some peptide hormones have complex tertiary structures; for example, glycoproteins are composed of more than one peptide chain. Oxytocin and arginine vasopressin, two of the posterior pituitary hormones, have ring structures linked by disulphide bridges. Despite being remarkably similar in structure, they have very different physiological roles. The gonadotrophins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), TSH and human chorionic gonadotrophin (hCG) also have two chains (Figure 10.2). However, these α - and β -subunits are synthesized quite separately from separate genes. The α -subunit of each is shared; it is the distinctive β -subunit of each that confers biological specificity.

Amino acid derivatives

These hormones are small water-soluble compounds. Melatonin is derived from tryptophan, whereas the tyrosine derivatives include the thyroid hormones, the catecholamines, and dopamine from the hypothalamic-anterior pituitary unit and the central nervous system. The catecholamines of the adrenal medulla, ephedrine and norepinephrine, are identical to the sympathetic neurotransmitters and, like peptide hormones, they are stored in secretory granules prior to release.

Steroids

Steroid hormones are lipid-soluble molecules derived from modification of the four-carbon ring structure of cholesterol (Figure 10.3). Steroids can be classified according to the

number of carbon atoms they possess: C-21 (progesterones, cortisol, aldosterone), C-19 (androgens) and C-18 (oestrogens). The common names used for steroids also adhere to a loose convention. The suffix -ol indicates an important hydroxyl group, as in cholesterol or cortisol, whereas the suffix -one indicates an important ketone (e.g. testosterone). The extra presence of -di, as in diol (e.g. oestradiol) or dione (e.g. androstenedione), reflects two of these

groups, respectively; -ene (androstenedione) within the name indicates a significant double bond in the steroid nucleus.

Regulation of Hormone Secretion and Action

Regulation and control of hormones is essential, and underpins not only the function of many endocrine systems but also their clinical investigation (Figure 10.4). Hormones utilize a variety of differential regulatory mechanisms.

Simple control

An elementary control system is one in which the signal itself is limited, either in magnitude or duration, so as to induce only a transient response. Refinement allows discrimination of a positive signal from background 'noise' to ensure that the target cell cannot or does not respond below a certain threshold level. An example of this is the pulsatile release of gonadotrophin-releasing hormone (GnRH) from the hypothalamus. Similarly, although uterine epithelial cells have receptors for oestrogen, androgen, glucocorticoid and progesterone, there is no progestational response because progesterone is not produced in the first half of the menstrual cycle.

Negative feedback

Negative feedback is the most common type of regulation used by biological systems. The hormone acts on the target cell to stimulate a response that inhibits the first hormone. An extension of this scenario exists for many of the hypothalamic–pituitary–end organ axes; for example, corticotrophin-releasing hormone from the hypothalamus stimulates the release of anterior pituitary adrenocorticotrophic hormone (ACTH) to increase peripheral cortisol production, which feeds back to the anterior pituitary and hypothalamus to reduce the original secretions.

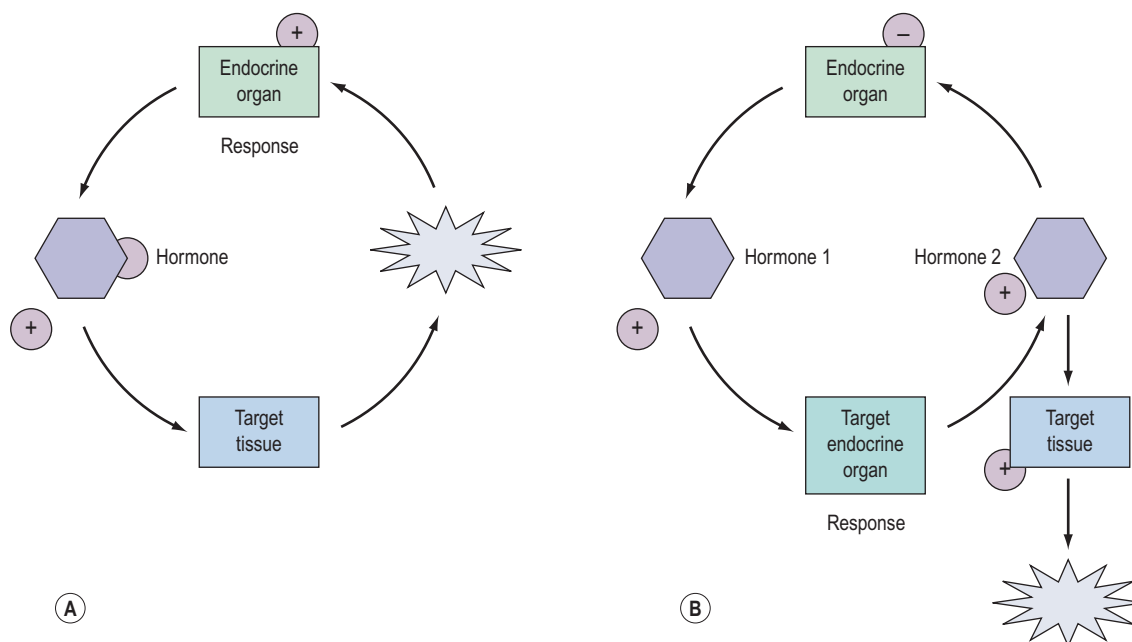

Figure 10.4 Two simplified models of hormone synthesis, action and feedback. (A) The endocrine organ releases a hormone which acts on the target tissue to stimulate (+) or inhibit (–) a response. The response may feedback either to inhibit or stimulate the endocrine organ to decrease or increase the supply of the hormone, respectively. (B) The endocrine organ produces hormone 1, which acts on a second endocrine gland to release hormone 2. In turn, hormone 2 acts dually on the target tissue to induce a response and feeds back negatively on to the original endocrine organ to regulate release of hormone 1. This model is illustrative of the axes between the anterior pituitary and its peripheral endocrine targets.

Positive feedback

Under certain circumstances, hormones feedback to the pituitary to enhance, rather than inhibit, secretion of the primary hormone. For example, the action of oestrogen on the pituitary gland to induce the ovulatory surge of LH and FSH; or during childbirth, stretch receptors in the myometrium send neurological signals to the brain to stimulate oxytocin release. The role of oxytocin in the suckling–milk

ejection reflex is similar; a positive feedback loop that is only broken by cessation of the baby's feeding.

Inhibitory control

The secretion of some hormones is under inhibitory as well as stimulatory control. Dopamine prevents the secretion of prolactin, such that if dopamine secretion is diminished, prolactin secretion will increase. This complexity from dual

inhibitory and secretory control allows more precise regulation of hormone secretion.

Endocrine rhythms

Many of the body's activities show periodic or cyclical changes and may either be circadian (24-h cycle, e.g. cortisol), ultradian (<24-h cycle, e.g. GnRH) or infradian (>24-h cycle, e.g. menstrual cycle). Control of these rhythms commonly comes from the nervous system, and although some are independent of the environment, others are coordinated and entrained by external cues, such as the 24-h light/dark cycle that becomes temporarily disrupted in jetlag. Cortisol secretion is maximal between 0400 h and 0800 h as we awaken, and minimal as we go to bed. In contrast, growth hormone (GH) and prolactin are secreted maximally 1 h after going to sleep. Clinically, knowledge of endocrine rhythms is important as analyses of hormones must take daily variation into account.

Availability of the hormone to a cell

A hormone can be present in the blood stream but unavailable to the target cell. A hormone circulating in the blood stream, not attached to a binding protein, readily enters cells by simple diffusion. However, most of the steroid hormones circulate bound to protein carriers, such as sex-hormone-binding globulin (SHBG), because their cholesterol origin makes them hydrophobic (King 1988). Consequently, they are generally unavailable, and alterations in the amount of circulating binding globulins can modulate the biological activities of each of their respective hormones. For example, approximately 40% of circulating oestrogen is bound to SHBG, and the remainder is bound to albumin and membrane proteins (Hovarth 1992). As testosterone is largely (80%) bound to SHBG and 19% is loosely bound to albumin, its androgenicity is mainly dependent upon the unbound fraction and partly upon the fraction associated with albumin. SHBG production in the liver is decreased by androgens, hence the binding capacity in men is lower than in normal women. In a hirsute woman, the SHBG level is depressed by the excess androgen, and the percentage of free and therefore active testosterone is elevated (Nestler et al 1991).

Tissue distribution

The tissue distribution of hormone receptors also determines the scope of hormone action, and the presence or absence of a given receptor determines whether a cell will respond to a given class of steroids. For example, the TSH receptor is limited to the thyroid and therefore TSH action is restricted to the thyroid. A hormone can also modify its own and/or another steroid hormone's activity by regulating the concentration of receptors in a cell. This has the biological effect of increasing tissue response to the hormone if the receptor number is increased, and vice versa if the receptor number is decreased. Oestrogen, for example, increases target tissue responsiveness to itself by increasing the concentration of FSH receptors in granulosa cells (Hillier 1994). This process is important in the selection and maintenance of the dominant ovarian follicle in the menstrual cycle. In

order to respond to the ovulatory surge and become a 'successful' corpus luteum, the granulosa cells must acquire LH receptors. FSH induces LH receptor development on the granulosa cells of large antral follicles with oestrogen acting as chief coordinator. Progesterone, on the other hand, limits the tissue response to oestrogen by reducing, over time, the concentration of oestrogen receptors, hence its use in the prevention of endometrial hyperplasia and carcinoma (Studd and Wadsworth 2000).

Hormone Receptors

The clinical effects of hormones are mediated through the interaction of a hormone with its receptors. There are two principal superfamilies of hormone receptors. This broad classification is based on their cellular location and their characteristic features (Figure 10.5).

Cell surface receptors

Cell surface receptors are composed of three components, each with structural features, which reflect its location and function (Figure 10.6). The hormone acts as a ligand, with a ligand-binding pocket in the extracellular domain of the receptor being comparatively rich in cysteine residues that form internal disulphide bonds and repeated loops to ensure correct folding. This extracellular domain may also be cleaved for some hormones, and function as a binding protein in the circulation, thus limiting bioavailability (e.g. GH). The α -helical membrane-spanning domain is rich in the hydrophobic and uncharged amino acids, enabling it to be secured with the lipid bilayer. The C-terminal cytoplasmic domain either contains, or links to, separate catalytic systems which initiate the intracellular signals after hormone binding.

Stage 1. Availability of the receptor (up- and downregulation)

The cell's mechanism for sensing the low concentration of circulating trophic hormone is to have an extremely large number of receptors but to require only a very small percentage (as little as 1%) to be occupied by the hormone for its action to be evident (Sairam and Bhargavi 1985). Positive and negative modulation of receptor numbers by hormones is known as up- and downregulation. The mechanism of upregulation is unclear, but prolactin and GnRH, for example, can increase the concentration of their own receptors in the cell membrane (Katt et al 1985).

In downregulation, an excess concentration of a trophic hormone, such as LH or GnRH, results in a loss of receptors on the cell membranes and therefore a decrease in biological response. This process occurs by internalization of the receptors, and is the main biological mechanism by which the activity of polypeptide hormones is limited (Ron-El et al 2000). Thus the formation of the hormone-receptor complex on the cell surface initiates the cellular response, and the internalization of the complex (with eventual degradation of the hormone) terminates the response. It therefore appears that the principal reason for the pulsatile secretion of trophic hormones is to avoid downregulation and to maintain

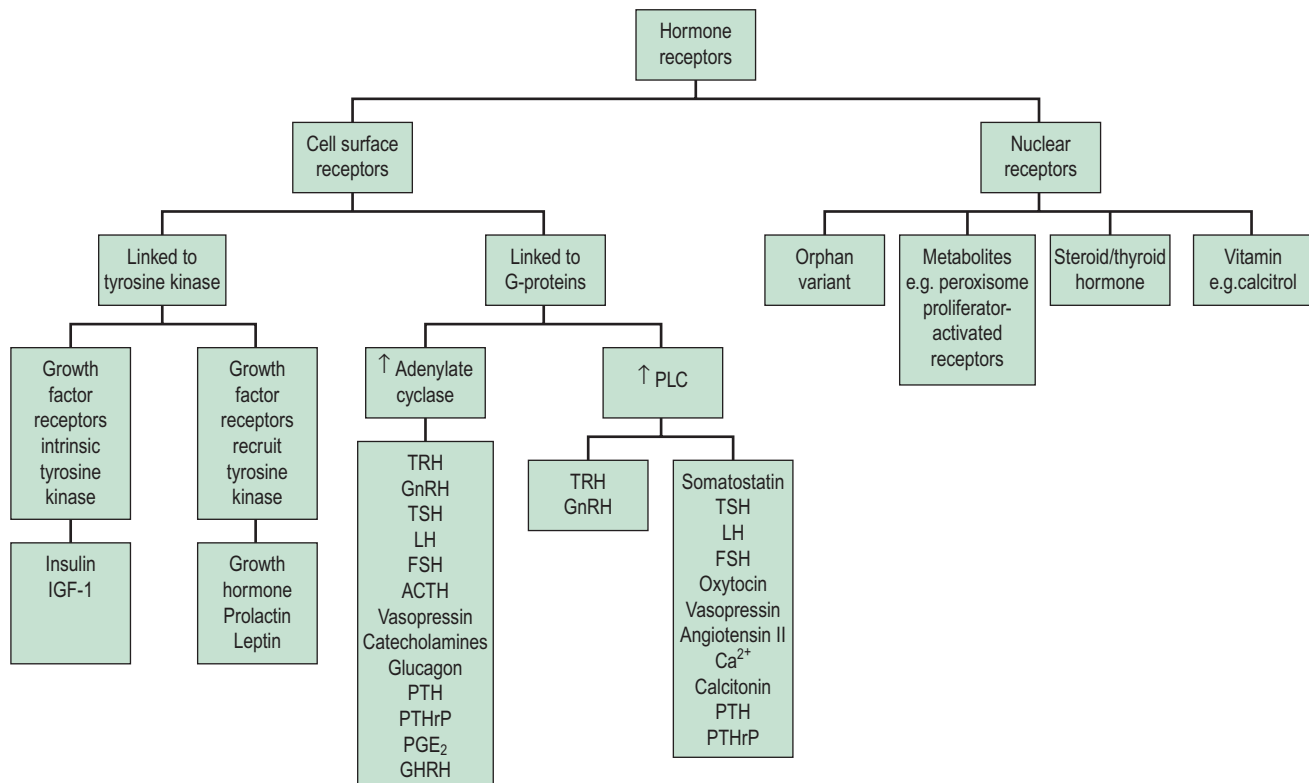

Figure 10.5 The different classes of hormone receptor. Some receptors can link to different G-proteins, which couple to either adenylate cyclase or phospholipase C (PLC). IGF-1, insulin-like growth factor-1; TRH, thyrotropin-releasing hormone; GnRH, gonadotrophin-releasing hormone; TSH, thyroid-stimulating hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; ACTH, adrenocorticotrophic hormone; PTH, parathyroid hormone; PTHrP, parathyroid-hormone-related peptide; PGE₂, prostaglandin E₂; GHRH, growth-hormone-releasing hormone.

adequate receptor numbers. The pulse frequency, therefore, is a key factor in regulating receptor number.

It is believed that receptors are randomly inserted into the cell membrane after intracellular synthesis. They have two important sites — an external binding site, which is specific for a polypeptide hormone, and an internal site, which plays a role in the process of internalization (Kaplan 1981). When a hormone binds to the receptor and a high concentration of the hormone is present in the circulation, the hormone–receptor complex moves laterally in the cell membrane by a process called ‘lateral migration’ to a specialized area, the coated pit, the internal margin of which has a brush border (Goldstein et al 1979). Lateral migration, which takes minutes rather than seconds, thus concentrates hormone–receptor complexes in the coated pit, a process referred to as ‘clustering’ (Figure 10.7). When fully occupied, the coated pit invaginates, ‘pinches off’ and enters the cell as a vesicle. The coated vesicle is delivered to the lysosomes where it undergoes degradation, releasing the hormone receptors. The receptors may be recycled to the cell membranes and used again, or the receptor and hormone may be metabolized, thus decreasing the hormone’s biological activity. This process is called ‘receptor-mediated endocytosis’ (Goldstein et al 1979; Figure 10.8).

As well as downregulation of polypeptide hormone receptors, the process of internalization can be utilized for other cellular metabolic events, including the transfer of vital

substances into the cell, such as iron and vitamins. Hence, cell membrane receptors can be separated into two classes. Class I receptors are distributed in the cell membrane and transmit information to modify cell behaviour for these receptors. Internalization is a method for downregulation and recycling is not usually a feature. Hormones which utilize this category of receptor include FSH, LH, hCG, GnRH, TSH and insulin (Kaplan 1981). Class II receptors are located in the coated pits. Binding leads to internalization, which provides the cell with the required ligands or removes noxious agents from the biological fluid bathing the cell. These receptors are spared from degradation and can be recycled. Examples of this category include low-density lipoproteins, which supply cholesterol to steroid-producing cells (Parinaud et al 1987), and transfer of immunoglobulins across the placenta to provide fetal immunity.

Stage 2. Binding of the hormone to the receptor

Notably hormone–receptor systems demonstrate standard kinetics and are saturable and reversible (Figure 10.9). Consequently, the dissociation rate of the hormone and its receptor is an important component of the biological response, as the biological activity of the hormone is only maintained while the hormone–receptor complex is maintained. Hormones that are structurally similar may have

Figure 10.6 (A) Three classes of membrane receptor are shown, illustrating the classic nuclear steroid hormone receptor associated with a caveola. (Aa) The receptor is technically outside the cell and is associated with the outer surface of the plasma membrane in the flask of the caveola. (Ab) The receptor is tethered by a scaffolding protein to the plasma membrane on the inner surface of a caveola. (Ac) The receptor is tethered to the caveolae by a palmitic acid molecule that is esterified to a receptor Ser or Thr with the fatty acid side chain 'inserted' into the membrane (palmitoylation). (B) A G-protein coupled receptor with its ligand-binding domain on the outside of the cell and a seven-membrane-spanning peptide transition followed by an intracellular peptide domain that can bind G and proteins. (C) A single-membrane-spanning receptor with intrinsic kinase activity that might be functional as a monomer. (D) As for C except a homodimer. Caveolae are flask-shaped membrane invaginations present in the outer cell membrane of many cells; they are believed to serve as a 'platform' to accumulate or 'dock' signal-transduction-related molecules. The signal-transduction systems are listed as candidates for mediating rapid responses to steroid. The two ovals with Ras-GTP and c-Raf 'touching' are to suggest that c-Raf was recruited to the complex. AC, adenylyl cyclase; DAG, diacylglycerol; EGFR, epidermal growth factor receptor; e-NOS, endothelial nitric oxide synthase; IP₃, inositol triphosphate; MAP, mitogen-activated protein; PI 3-kinase, phosphatidylinositol 3 kinase; PIP₃, phosphatidylinositol triphosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C. Reproduced with permission from Norman et al.; *Steroid-hormone rapid actions, membrane receptors and a conformational ensemble model*, *Nature Reviews Drug Discovery* 3, 27–41 (January 2004).

Figure 10.7 Structure of a coated pit, illustrating lateral migration.

some overlap in biological activity. For example, the similarity in structure between GH and prolactin means that GH has a lactogenic action whilst prolactin has some growth-promoting activity and stimulates somatomedin production.

The glycoprotein hormones (LH, FSH, TSH and hCG) share an identical α -chain and require another portion, the β -chain, to confer the specificity inherent in the relationship between hormones and their receptors. The β -subunits differ in both amino acid and carbohydrate content, and the chemical composition may be altered under certain conditions, thereby affecting the affinity of the hormone and its receptor (Willey 1999).

Stage 3. Signal transduction

On binding of a hormone to its cell surface receptor, protein phosphorylation and the generation of 'second messengers' mediates a cascade of cytoplasmic and cellular responses. This multistep cascade facilitates amplification of the cellular response to the hormone binding to a receptor, as many

Figure 10.8 Possible routes of receptor and hormone during receptor-mediated endocytosis.

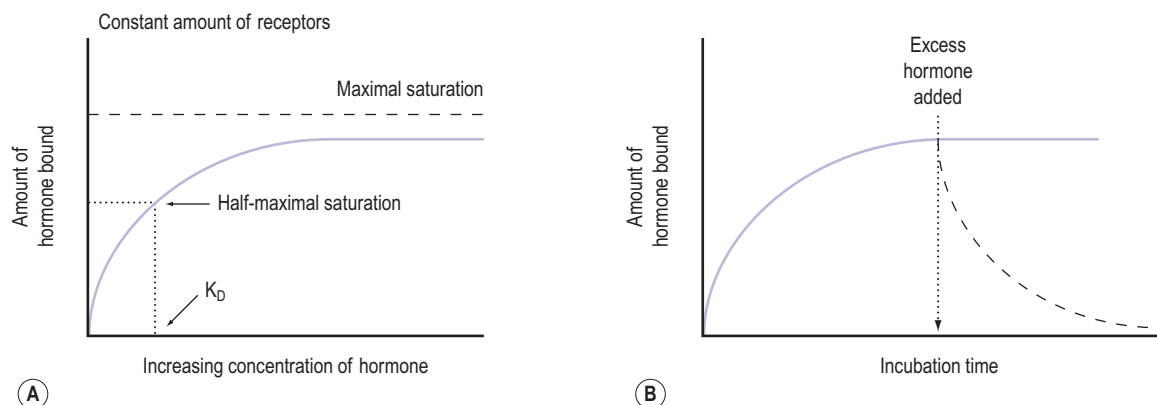

Figure 10.9 Pharmacokinetics of hormone receptors demonstrating that hormone–receptor systems are saturable and reversible. (A) Increasing amounts of hormone are incubated with a constant amount of receptor. The amount of bound hormone increases as more is added until the system becomes saturated. At this point, further addition of hormone fails to increase the amount bound to receptors. The concentration of hormone that is required for half-maximal saturation of the receptors is equal to the dissociation constant (K_D) of the hormone–receptor interaction. (B) Constant amounts of hormone and receptors are incubated together for different times. The amount of hormone bound increases with time until it reaches a plateau, when the bound and free hormone have reached a dynamic equilibrium. By adding further excess hormone, there is competition for the binding sites and the amount of the first hormone bound decreases with time (dashed line).

Adapted from Holt RIG, Hanley NA 2007. *Essential Endocrinology and Diabetes*, 5th edn. Blackwell Publishing, Massachusetts.

second messenger molecules are produced for each hormone–receptor complex. The cell surface receptors may be classified into two groups according to the second messenger and signalling cascades that are stimulated: (1) tyrosine kinase receptors and (2) G-protein coupled receptors (Figure 10.5).

Tyrosine kinase receptors

Initial phosphorylation of proteins is a key molecular switch, and approximately 10% of proteins are phosphorylated at any given time in a mammalian cell. Phosphorylation occurs when the polar hydroxyl group of serine, threonine or tyrosine has a phosphate group added from an ATP molecule in a reaction catalysed by a 'kinase' enzyme. The phosphorylation induces a conformational change in the three-dimensional shape of the protein, and the phosphorylated protein may also act as a kinase and phosphorylate the next protein in the sequence, creating a phosphorylation cascade.

Phosphorylation of tyrosine kinase receptors can occur through: (i) intrinsic tyrosine kinase activity located in the cytosolic domain of the receptor; or (ii) separate tyrosine kinases recruited after receptor activation. By either mechanism, conformation change induced by phosphorylation creates 'docking' sites for other proteins. Frequently, this occurs via conserved motifs within the target protein known as 'SH2' or 'SH3' domains. These domains may be involved in the activation of downstream kinases, or they may play a more passive role, stabilizing signalling proteins within a phosphorylation cascade.

The subfamily of receptors which recruit tyrosine kinase activity includes those that bind GH, prolactin and leptin, and also includes those for numerous cytokines and erythropoietin. The basic receptor composition, with major homology between family members in the extracellular domain, is the same for the other membrane-spanning receptors (Figure 10.6). Notably, similar mechanisms govern GH and prolactin receptor binding and signal transduction. Two different sites on the hormone are capable of binding receptors. The hormone–receptor interaction of the first leads to the binding of the second to another receptor molecule. It is the close proximity of the two receptor molecules which leads to dimerization of their cytoplasmic regions and signal transduction. With the exception of the receptor for erythropoietin, other cytokine receptors tend to form heterodimers with diverse partner proteins.

Activation of these hormone receptors rapidly recruits members of the Janus family of tyrosine kinases. The four members of the family contain distinctive, tandem kinase domains at their carboxy terminals leading to their name 'Janus-associated kinase' (JAK1–4) after the two-faced Roman deity, Janus. GH and prolactin receptors tend to associate with JAK2 and it is probable that their dimerization brings together two JAK2 molecules that cross-phosphorylate each other. The major downstream substrates of JAK are the STAT family of proteins (hence the term 'JAK-STAT' signalling). The name 'STAT' comes from their dual function: (i) signal transduction, located in the cytoplasm; and (ii) nuclear activation of transcription. Both activities rely on phosphorylation by JAK, facilitated by SH2-mediated docking on to the hormone receptor. Phosphorylated STAT proteins dissociated from the occupied receptor–kinase

complex and then themselves dimerize to gain access to the nucleus. There, they activate genes regulating proliferation of the differentiation status of the target cell. One of the major targets is insulin-like growth factor 1. JAK signalling does not focus exclusively on STAT. GH receptor occupancy also stimulates MAPK (mitogen-activated protein kinase) and PI 3-kinase pathways. This overlap may account for some of the rapid metabolic effects of GH.

G-protein coupled receptors

G-protein coupled receptors are the most common subset of cell surface receptors, with more than 140 types. The most striking structural feature of all these receptors lies in the transmembrane domain, which comprises hydrophobic helices which cross the lipid bilayer of the plasma membrane seven times before being coupled to guanine (G)-proteins at the inner surface of the cell membrane. This coupling leads to the generation of intracellular second messengers such as cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG) and inositol triphosphate (IP₃) — the latter two arising from phosphatidylinositol (PI) metabolism.

Signalling of G-protein receptors is mediated by hydrolysis of GTP (guanosine triphosphate) to GDP (guanosine diphosphate) (Figure 10.10). In their resting state, the G-proteins exist in the cell membrane as heterotrimeric complexes with α -, β - and γ -subunits. In practice, the β - and γ -subunits associate with such affinity that the functional units are G α and G β/γ . When the hormone binds to the receptor, this causes a conformational change in receptor structure, which in turn causes a conformational change in the α -subunit allowing it to dissociate from the heterotrimeric complex and bind to a downstream catalytic unit, either adenylate cyclase facilitating the generation of cAMP or phospholipase C (PLC) for the production of DAG/IP₃. The energy to activate these targets comes from the cleavage of phosphate from GTP, thereby regenerating G α -GDP. This ensures that it is no longer associated with adenylate cyclase or PLC, thereby switching off the cascade and recycling the G α -GDP back to the start.

Although there are over 20 isoforms of the G α -subunit, allowing a wide variety of cellular responses, they can be grouped into four major subfamilies. However, more than half of G-protein coupled receptors can interact with different G α -subunits and thus modulate contrasting, and sometimes conflicting, intracellular second messenger systems. In part, this promiscuity can be attributed to the degree of hormonal stimulation or activation of different receptor subtypes. For instance, at low concentrations, LH receptors associate with G α_s to activate adenylate cyclase, whereas higher concentrations recruit G α_q to activate PLC.

Second messenger pathways: cyclic adenosine monophosphate

Activation of membrane-bound adenylate cyclase catalyses the conversion of ATP to the potent second messenger cAMP. cAMP interacts with protein kinase A (PKA) to unmask its catalytic site, which phosphorylates serine and threonine residues on a transcription factor called 'cAMP response element binding protein' (CREB). CREB then translocates to the nucleus where it binds to a short

Figure 10.10 G-protein coupled receptors. The extracellular domain is ligand specific and hence less conserved across family members. The transmembrane domain has a characteristic heptahelical structure, most of which is embedded in the cell membrane and provides a hydrophobic core. Conserved cysteine residues can form a disulphide bridge between the second and third extracellular loops. The cytoplasmic domain links the receptor to the signal-transducing G-proteins and, in this example, is linked to membrane-bound adenylate cyclase. The activation of adenylate cyclase is shown c to C*.

palindromic sequence in the promoter regions of cAMP-regulated genes. This signalling pathway regulates major metabolic pathways, including those for lipolysis, glycogenolysis and steroidogenesis.

The cAMP response is terminated by a large family of phosphodiesterases (PDEs), which can be activated by a variety of systems including phosphorylation of PKA in a negative feedback loop. PDEs rapidly hydrolyse cAMP to the inactive 5'AMP. In addition, activated PKA can phosphorylate serine and threonine residues of the G-protein coupled receptor to cause receptor desensitization.

Second messenger pathways: diacylglycerol and Ca^{2+}

Signalling by some hormones including GnRH and oxytocin is through recruitment of G-protein complexes containing the $\text{G}_q\alpha$ -subunit. This activates membrane-associated PLC,

which catalyses the conversion of PI 4,5-bisphosphate to DAG and IP_3 . IP_3 stimulates the transient release of calcium from the endoplasmic reticulum to activate several calcium-sensitive enzymes, including the protein kinase, calmodulin and some isoforms of protein kinase C (PKC). Calcium ions also activate cytosolic guanylate cyclase, an enzyme that catalyses the formation of cyclic guanosine monophosphate.

The major target of DAG signalling is PKC, which activates phospholipase A2 to liberate arachidonate from phospholipids and generate potent eicosanoids, including thromboxanes, leucotrienes, lipoxins and prostaglandins. The latter are well-recognized paracrine and autocrine mediators capable of amplifying or prolonging a response to a hormone stimulus.

Nuclear receptors

The nuclear receptors are classified by their ligands, which are small lipophilic molecules that diffuse across the plasma membrane of target cells. The receptors, encoded by a single gene, typically bind DNA and function as transcription factors (Figure 10.11). Distinct polypeptide-encoding regions can be identified, for which evolutionary conservation can be as high as 60–90%. Many nuclear receptors exist for which no endogenous ligand has been identified, and these are termed 'orphan' nuclear receptors. In addition, some variant receptors have atypical DNA-binding domains and potentially function via indirect interaction with the genome.

The receptor family predominantly resides in the nucleus, although increasingly nuclear import and export appears to be an important regulatory mechanism, as has been long recognized for the glucocorticoid receptor. The receptors have their primary effect by regulating the expression of specific target genes. Consequently, this need for transcription and translation to elicit a biological effect means that cellular responses are relatively slow compared with cell surface receptor signalling. For example, high midcycle levels of oestradiol from the ovary lead to the increase in LH synthesis and secretion by the anterior pituitary that results in ovulation (Hillier 1994).

Target cell conversion of hormones destined for nuclear receptors

A further characteristic of several nuclear hormone receptors includes enzymatic modification of the ligand within the target cell. This converts the circulating hormone into a more, or less, potent metabolite prior to receptor binding. An extreme example of this is the inactivation of cortisol to cortisone by type 2 11β -hydroxysteroid dehydrogenase, which occurs in the placenta, thereby minimizing exposure of the fetus to maternal cortisol.

Hormone specificity of the receptor

This is the most important factor which determines specificity of action and occurs at two levels (King 1988). The presence or absence of a given receptor determines whether or not a cell will respond to a given class of steroids, whilst hormone specificity controls which particular compound is active. For example, the oestrogen receptor, which has the greatest specificity, binds oestradiol 10 times more efficiently

Figure 10.11 Steroid hormone action. Free steroid in equilibrium with that bound to protein (A) diffuses across the target cell membrane (B). Binding to its receptor may occur in the cytoplasm or in the cell nucleus. The activated hormone–receptor complex now present in the nucleus (C) binds to the hormone response element (HRE) of its largest target genes (D). This interaction promotes DNA-dependent RNA polymerase to start transcription (E) of mRNA. Post-transcriptional modification and splicing sees the mRNA exit the nucleus (F) for translation into protein on ribosomes. Post-translational modification provides the final protein (G).

Adapted from Holt RIG, Hanley NA 2007. *Essential Endocrinology and Diabetes*, 5th edn. Blackwell Publishing, Massachusetts.

than oestrone and about 1000 times more efficiently than the androgen, testosterone, whilst progesterone and cortisol are not recognized at all (Garcia and Rochefort 1977). This recognition specificity is a reflection of the different affinities that the receptor has for the different hormone structures. In biological terms, this means that oestradiol is more active than oestrone, whilst testosterone can have oestrogenic effects but only at pharmacological concentrations.

It is notable that the oestrogen receptor is not a single entity and that it is not restricted to the reproductive system. There are two receptors that can bind to oestrogen, the oestrogen receptor alpha (ER α) and the oestrogen receptor beta (ER β). These receptors are functionally distinct, having different tissue distributions and different ligand activation, and as such play different roles in gene activation. Both ER α and ER β interact with the same oestrogen ligand, oestradiol-17 β , but they behave differently, sometimes even causing opposing effects. For example, ligand-bound ER α was found to activate transcription, while ligand-bound ER β inhibited transcription from the AP1 site. They can respond to synthetic ligands in different ways as well; for instance, THC acts as an ER α agonist and as an ER β antagonist. ER β can act as a dominant inhibitor of ER α transcriptional activity in cells that express both receptors. Notably, the binding of oestradiol or selective oestrogen receptor modulators such as raloxifene (see below) to the receptor leads to oestrogen agonism and antagonism according to which receptor the ligand has bound to (see below) (Kearney and Purdie 2000).

Androgen, glucocorticoid, progesterone and mineralocorticoid receptors are less precise in their binding requirements than the oestrogen receptor (Beato and Klug 2000). For example, many progestogens, especially the synthetic ones, bind to both progesterone and androgen receptors when present in pharmacological concentrations. This dual specificity is reflected in the biological activities of the compounds. For example, the practice of giving synthetic progestogens to pregnant women to prevent miscarriage resulted in some of their offspring having clinical features associated with androgen exposure (Aarskog 1979). The androgenic side-effects of the synthetic progestogens used in the oral contraceptive pill are another example.

Nuclear localization, DNA binding and transcriptional activation

In their resting state, unbound steroid hormone receptors associate with heat-shock proteins, which obscure the DNA-binding domain so that they cannot bind the genome. On binding of steroid to the receptor, there is a conformational change and the heat-shock protein is dissociated, revealing two polypeptide loops stabilized by zinc ions, known as zinc fingers, facilitating dimerization and the binding of cofactors which will promote (coactivators) or inhibit (corepressors) the interaction of the receptor to its target genes. The receptors then affect gene expression by either binding directly to DNA target genes through specific hormone response

elements, or by binding to other DNA-bound transcription factors such as AP1, SP1 or NF- κ B. If the endpoint is transcriptional activation, binding of the hormone will result in recruitment of DNA-dependent RNA polymerase.

Clinical Assays

This section considers assay methodology for the endocrinological investigations commonly used in gynaecological practice. An understanding of basic methodology permits the clinician to have confidence in the selection of specific laboratory tests, and leads to a greater understanding of the assay for better interpretation of results (Chard 1987).

An assay determines the amount of a particular constituent of a mixture. The three types of analytical procedure commonly available in clinical practice are physicochemical assays, bioassays and binding assays.

Physicochemical assays

Some aspect of the physicochemical properties of a compound is utilized for its quantification. These are the assays used to measure some steroid hormones or intermediaries from their biosynthetic pathways. Techniques such as high-performance liquid chromatography or gas chromatography coupled with mass spectrometry are becoming increasingly used, and provide a definitive approach to the identification and quantification of hormones based on their physical characteristics.

Bioassays

Detection or quantification is dependent on the biological actions of the compound. There are two forms of endocrine bioassay. In-vivo bioassays investigate the biological potency of a hormone following its administration to an animal and quantification of a specific response. For example, human pregnancy could be diagnosed by the injection of maternal urine into the Black African Toad. If a high concentration of hCG was present in the urine, the toad would lay eggs. In-vitro bioassays measure biological effects when hormone is added to an isolated laboratory preparation of the target tissue. For example, in the bioassay of prolactin, when neural tumour cells grown in culture are exposed to prolactin, they replicate.

Binding assays

These assays involve the combination of the compound, for example, an antigen, with a binding substance, for example, an antibody, which is added in a fixed amount to the solution. The distribution of the antigen between the bound and free phases is directly related to the total amount of antigen present, and provides a means for quantifying the latter (Figure 10.12). Binding assays can be further subdivided into three groups: receptor assays, competitive protein-binding assays and immunoassays.

Receptor assays

A specific site on the surface of a tissue acts as the binding agent for a particular hormone; for example, oestrogen

Figure 10.12 Distribution of free (F) and bound (B) antigen in the presence of a fixed amount of antibody.

receptors in breast tissue. The principles and designs are similar to immunoassays, with the hormone–receptor complex replacing the hormone–antibody complex. The hormone receptors and hence the assays derived from them have high affinity and hormone specificity, often generating favourable sensitivity, precision and sample capacity. They also bridge the gap between the bioassays and immunoassays.

Competitive protein-binding assays

A naturally occurring binding protein, such as SHBG, is used as the binder to quantify the amount of hormone present.

Immunoassays

A reaction, which reaches equilibrium, occurs between the hormone to be measured (antigen) and an antibody to monitor the reaction. A 'tracer' is attached to either the antigen or antibody to generate a quantitative signal. Non-isotopic tracers have superseded isotopic (radio-active) tracers, e.g. ^{125}I , and are typically based on enzymatic action such as fluorescence.

The basic binding reaction can be subdivided into two categories, based on whether the antibody is present in a limited concentration or whether it is present in excess. If varying concentrations of the labelled antigen react with an excess amount of antibody (Figure 10.13), it is termed an 'immunometric assay'. The principle of an immunometric assay is that a constant amount of antibody is added with increasing known amounts of the reference hormone. After incubation, the amount of hormone bound to the antibody is detected by adding, to all the tubes, an excess amount of a second labelled anti-hormone antibody. The second antibody is directed against a different antigenic site on the hormone from the first antibody. Thus, a triple complex is formed, with the hormone sandwiched between the two antibodies. The unbound fraction of the second antibody is removed, leaving the amount of triple complex to be determined by quantifying the bound label; for example, by measuring the radioactivity or fluorescence emitted. This emission is plotted against the increasing known amount of hormone standard to generate a calibration curve. To determine the standard curve with precision, against which patient samples can be interpolated, usually five to eight

Figure 10.13 (A) Immunometric assay with an excess of antibody. (B) Increasing concentrations of antigen give rise to a corresponding increase in bound antibody.

different concentrations are used. The immunometric assay is only suitable when the hormone to be measured is large enough to permit the discrete binding of two antibodies.

Enzymeimmunoassay, enzymeimmunoassay and enzyme-labelled immunosorbent assay are currently the most widely used non-isotopic labels. Small quantities of antigen can be quantified by studying enzymatic substrate conversion that leads to a colour change. The colour formation can be a simple yes/no answer (Figure 10.14) as in a rapid pregnancy test, or the intensity of colour can be used to quantify the patient sample. The second marker antibody will not be bound, so following the wash step, it will not be present to react with its substrate.

Measurement and Action of Individual Hormones

In the interpretation of hormonal tests, it is important to be aware of local laboratory ranges and timing of the sample with respect to circadian and menstrual cycles, and also gestational age. The action of the individual hormones is discussed in further detail in the relevant chapters.

Anterior pituitary hormones

Follicle-stimulating hormone

Due to the marked fluctuations in FSH levels in a normal ovulatory cycle, timing of the blood sample in relation to ovulation is required to interpret results (Figure 10.15). The level can be as low as 0.5 IU/l at the luteal phase nadir and as high as 20 IU/l at the midcycle peak. However, values below 1 IU/l are associated with hypothalamic pituitary failure, and values of 20 IU/l or above indicate ovarian failure, as in the menopause.

In addition, FSH values within the wide range of normal can be associated with absent ovarian function if the production is below the threshold of follicular development for that patient; in other words, a normal result does not guarantee

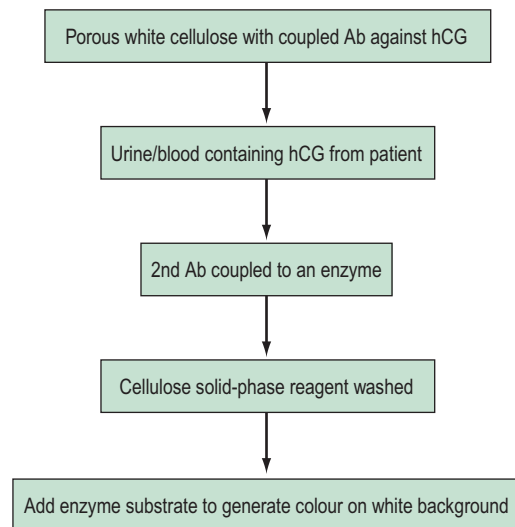

Figure 10.14 Principle of rapid pregnancy test (tube test) using non-isotopic reagents. hCG, human chorionic gonadotrophin; Ab, antibody.

a normal endocrinological pattern in an individual patient. Fluctuating FSH levels mean that the investigation needs to be performed in the early follicular phase, particularly in a perimenopausal patient.

Luteinizing hormone

As for FSH, timing the sample in relation to the phase of the ovulatory cycle is vital (Figure 10.15). For example, the ovulatory surge is taken as above 20 IU/l. However, in polycystic ovary disease, a raised LH (13–25 IU/l) with normal FSH values is characteristic. Therefore, a raised LH in the early to midfollicular phase is of more significance than a midcycle raised LH. The LH level is within the normal range in a significant number of women with polycystic ovary disease, and the diagnosis requires the use of other tests. As the prospective timing of ovulation using the LH peak presents the

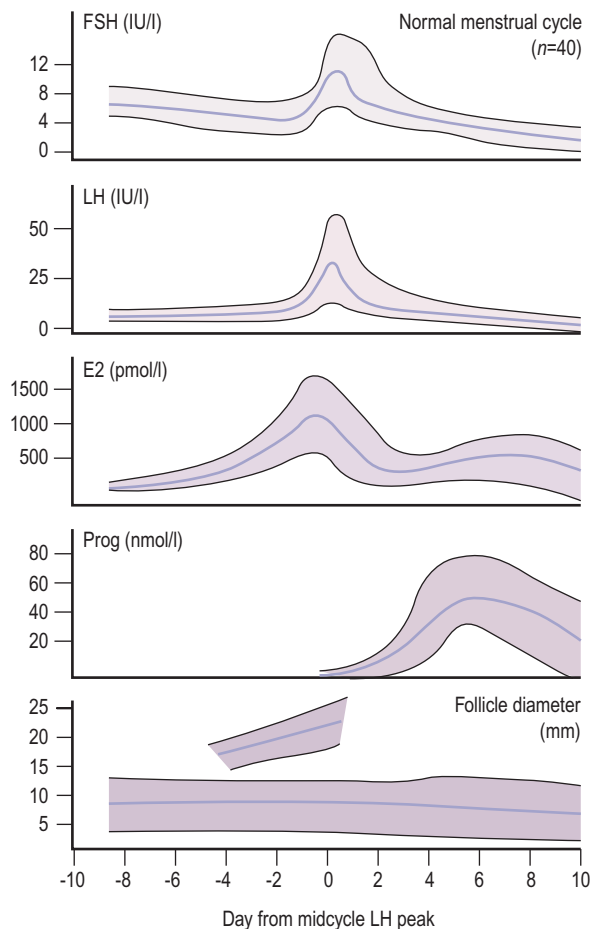

Figure 10.15 Serum concentrations (mean and 95 centiles) of follicle-stimulating hormone (FSH), luteinizing hormone (LH), oestradiol (E2) and progesterone (Prog) in relation to the size of the dominant follicle in 40 spontaneously ovulating women with regular cycles.

difficulty that the peak cannot be identified until the next value significantly lower than the peak is observed, clinical action is taken on the basis of the first definite rise in LH values (LH surge) rather than on the peak, which usually occurs a day later. This initial rise in LH underlies the mechanism of home ovulation kits using urine rather than blood samples.

Prolactin

Prolactin levels are influenced by the time of day when blood is collected and are increased by stress (including venepuncture). Transient rises can occur at ovulation. Therefore, a small elevation above the normal range can occur in normal women. Such a rise should be judged in the clinical setting. If a woman has a normal menstrual cycle, the result is unlikely to be significant. However, if she is amenorrhoeic, she should be investigated further.

Growth hormone

GH is secreted in short bursts, most of which occur in the first part of the night. These bursts are more frequent in children, so the results vary depending upon timing and age.

Secretion is also stimulated by stress and hypoglycaemia, and is inhibited by glucose and corticosteroids.

Thyroid-stimulating hormone

Normal levels of TSH range from 0.4 to 5 mmol/l. The measurement of tetraiodothyronine (T4) and TSH provides the most accurate assessment of thyroid functions. Levels also change across gestation, and specific pregnancy ranges are required to ensure adequate thyroxine replacement in women with hypothyroidism. When using thyroid hormone replacement therapy, both TSH and T4 should be measured because TSH alone cannot detect overdosage.

Thyroid hormones

Deficiency of the thyroid hormones triiodothyronine (T3) and T4 leads to anovulation associated with increased gonadotrophin levels. Therefore, it is important to assess thyroid function in the work up of oligoamenorrhoea and prior to diagnosing premature ovarian failure.

Circulating thyroid hormone is tightly bound to a group of proteins, chiefly thyroxine globulin. Oestrogen produces a rise in thyroxine-binding capacity and, therefore, thyroid function tests are affected by pregnancy and oestrogen-containing medications such as the contraceptive pill. Consequently, a raised thyroxine level does not mean that the free thyroxine concentration (the unbound and metabolically active hormone) is above the normal range. Due to the peripheral source of T3, its levels are not a direct reflection of thyroid secretion. In addition, T3 levels may be normal despite the presence of goitre with elevated TSH and depressed T4 concentrations, as T4 plays an instrumental role in TSH regulation. Therefore, measurement of free T4 and TSH provides the most accurate assessment of thyroid function. Measurement of T3 is important for the occasional case of hyperthyroidism due to excessive production of T3 with normal T4 levels (T3 toxicosis). Drugs taken orally for cholecystograms inhibit the peripheral conversion of T4 to T3, and can disrupt normal thyroid levels (giving elevated T4) for up to 30 days after administration.

Adrenal hormones

The adrenal cortex comprises three morphologically and functionally distinct regions. The outermost region (zona glomerulosa) secretes aldosterone. The zona fasciculata is the intermediate region and produces cortisol, which will be dealt with here. The zona reticularis encircles the medulla and synthesizes oestrogens and androgens.

Cortisol

Normal levels of cortisol in adults at 0900 h range from 300 to 700 nmol/l. If a 24-h urine collection is used, it is necessary to ensure that a complete collection has been obtained. The measurement of creatinine excretion will identify whether a collection is incomplete. As blood levels of cortisol vary greatly over a 24-h period, sample timing is important. Blood levels are highest in the morning and lowest in the evening. Most laboratories' normal values are based on sampling at 0900 h.

Dynamic testing of cortisol secretion by the adrenal glands is possible by means of a short synacthen test, whereby ACTH is administered intravenously after fasting, and the cortisol response measured in peripheral blood samples is quantified prior to ACTH administration and after 30 and 60 min.

Ovarian hormones

Oestradiol

Serum levels of oestradiol in spontaneous ovulation in relation to changes in FSH, LH, progesterone and the size of the dominant follicle are shown in Figure 10.15 (Macklon and Fauser 2000). There is a variation in oestradiol levels throughout the menstrual cycle. Results therefore need to be interpreted in relation to the timing of the sample in the cycle. Serum oestradiol levels in pregnancy range from 2 to 10 nmol/l in the first trimester and from 20 to 80 nmol/l in the third trimester. The major oestrogen in pregnancy is oestril.

Progesterone

Variations throughout the menstrual cycle can lead to difficulties in interpretation if the result is taken at an unidentified time in the cycle, particularly if a single progesterone level is taken as a marker of ovulation (Figure 10.15). Normally, results taken 5–8 days prior to the next menstruation are suitable for the detection of ovulation, so the patient should be asked to keep a record of the timing of the blood sample and her next menstrual period. A result >30 nmol/l indicates ovulation, even if timing is not known. Levels in the mother during pregnancy increase in parallel with the growth of the placenta, being 30–45, 70–150 and 150–600 nmol/l in the first, second and third trimesters, respectively. Maternal progesterone levels are related to the weight of the fetus and placenta at term.

Inhibin

In the female, inhibin is synthesized predominantly by ovarian granulosa cells. Inhibin levels increase in the late follicular phase, acting synergistically with oestradiol to inhibit FSH synthesis and release, although this is predominantly over-ridden by the preovulatory LH and FSH surge (Bevan and Scanlan 1998). Inhibins A and B are dimeric proteins capable of suppressing FSH, with inhibin B being the principal form produced by the Sertoli cells in the testis which inhibits pituitary FSH secretion. Activins A, B and AB are dimeric proteins which share β -subunits with inhibin but stimulate FSH (Groome et al 2001).

Testosterone

Testosterone levels in females are lower than in males (females 0.5–3.0 nmol/l, males 9–35 nmol/l). The reverse is the case for SHBG (females 39–103 nmol/l, males 17–50 nmol/l). Testosterone arises from a variety of sources in the female. Approximately 50% is derived from peripheral conversion of androstenedione (secreted by the adrenal cortex), while the adrenal gland and ovary contribute approximately equal amounts (25%) to the circulating levels

of testosterone, except at midcycle when the ovarian contribution increases by 10–15%. Approximately 80% of circulating testosterone is bound to SHBG.

Anti-Müllerian hormone

Anti-Müllerian hormone (AMH, Müllerian-inhibiting substance), a member of the transforming-growth factor- β family, has the primary role of regression of the Müllerian duct in the male fetus during early testis differentiation. However, expression of AMH persists after completion of the reproductive duct system in males, and furthermore commences in females, where it is produced by ovarian granulosa cells from early fetal life (Modi et al 2006). In females, AMH appears to have inhibitory effects upon the recruitment of primordial follicles (Durlinger et al 2002), and it may decrease the sensitivity of large preantral and small antral follicles to FSH (Figure 10.16) (Durlinger et al 2001). However, recent analyses of human follicles examining AMH receptor expression suggests that inhibitory effects at the earliest stages of development are unlikely (Rice et al 1997). Although AMH is initially observed in granulosa cells of primary follicles, maximal expression occurs in preantral and small antral follicles (Laven et al 2004, Weenen et al 2004). AMH expression declines as antral follicles increase in size, with nominal expression restricted to the granulosa cells of the cumulus (Weenen et al 2004). This loss of AMH expression during the FSH-dependent final stages of follicular growth, and the lack of expression by atretic follicles, suggests that basal levels of AMH may more accurately reflect the total developing follicular cohort, and consequently the potential ovarian response to FSH. Furthermore, AMH has been shown to be relatively stable across the menstrual cycle (La Marca et al 2010), consistent with its role reflecting the continuous, non-cyclic growth of small follicles in the ovary.

In harmony with the established relationship between age and declining ovarian reserve, AMH falls with increasing age (de Vet et al 2002). The clinical utility of AMH is its strong

Figure 10.16 Anti-Müllerian hormone (AMH) expression in the ovary. Rhesus macaque ovary stained for AMH by immunocytochemistry. Minimal expression in the primordial follicle, with increased expression by granulosa cells in the preantral and antral follicles. Ovarian stroma clearly negative. ability to predict ovarian response to FSH in cycles of assisted conception (Nelson et al 2007, 2009) and onset of the menopause (Sowers et al 2008).

Placenta

Human chorionic gonadotrophin

This is secreted by the blastocyst and appears in maternal blood shortly after implantation and then rises rapidly until 8 weeks' gestation. Levels show little change at 8–12 weeks' gestation, then decline to 18 weeks' gestation and remain fairly constant until term. There is some short-term variation in blood hCG levels but no circadian rhythm. At term, the levels in the female fetus are substantially higher than those in the male (Obiekwe and Chard 1983). The mechanisms which determine the levels of hCG in maternal blood are unknown.

A patient can continue to have a positive pregnancy test for at least 1 week after a miscarriage or therapeutic abortion due to the prolonged half-life of hCG; hCG may be detected up to 20 weeks later if sensitive assays are used. hCG measurements in blood and urine are used for the early detection of ectopic pregnancy, an increased risk of miscarriage, risk of embryos or fetuses with aneuploidy, prediction of pre-eclampsia or fetal growth restriction, and diagnosis or monitoring of trophoblast disease. The choice of assay for measurement of the prevalent form or proportion in relation to the intact hCG in any particular clinical setting is critical, as the complex cascade of enzymes involved in hCG secretion results in heterogeneous molecular forms (de Medeiros and Norman 2009). The synthesis of α - and β -subunits and their further glycosylation require different enzymes. After assembly, hCG reaches the cell surface and is secreted as a bioactive heterodimer. The hCG molecules are metabolized differently by the liver, ovary and kidney, but most of the hCG forms are excreted in the urine. It is clear that specific assays for intact hCG and its variants, α -hCG, β -hCG, hyperglycosylated hCG, nicked hCG and core fragment of β -hCG, have a wide spectrum of clinical implications (Cole 2009).

Pregnancy-associated plasma protein A

There is evidence that pregnancy-associated plasma protein A (PAPP-A) proteolyzes insulin-like growth factor binding protein-4, thereby regulating local insulin-like growth factor availability. In addition, PAPP-A can no longer be regarded

as 'pregnancy specific' (Boldt and Conover 2007). In pregnancy, PAPP-A can be detected in the maternal blood consistently from 6 to 8 weeks' gestation, with concentrations rising steadily throughout the pregnancy, but the mechanisms which regulate the synthesis of PAPP-A are not yet known. However, depressed serum levels of PAPP-A are seen in association with some fetal chromosomal abnormalities (trisomy 21, trisomy 18 and trisomy 13), Cornelia de Lange syndrome and ectopic pregnancy (El-Farra and Grudzinskas 1995, Kagan et al 2008). Maternal serum screening by maternal age, fetal nuchal translucency thickness, fetal heart rate, and maternal serum-free β -hCG and PAPP-A in the first trimester of pregnancy (11–13 weeks) will detect approximately 95% of pregnancies affected by trisomy 21, trisomy 18 and trisomy 13 (Kagan et al 2008). Serum PAPP-A levels are elevated in acute coronary syndromes and may be associated with adverse outcome (Schoos et al 2008).

Fetus

α -Fetoprotein

α -Fetoprotein (AFP) is synthesized by yolk sac, fetal liver and gastrointestinal tract. Its function is largely unknown; however, it is used as a marker in clinical practice for the identification of congenital abnormalities. Neural tube defects are associated with raised midtrimester levels of AFP, while Down's syndrome is associated with reduced midtrimester levels of AFP. The value of AFP varies with gestation and the number of fetuses present. The concentration of AFP in fetal serum rises rapidly to reach a peak at 12–14 weeks' gestation, at which time the levels are 2–3 g/l. Thereafter, it falls until term with a sharp drop at 32–34 weeks' gestation. In the mother, circulating AFP levels rise progressively to reach a peak at 32 weeks' gestation, and then decrease towards term.

The interpretation of normality of levels therefore depends upon gestation, and incorrect assessment of gestation could lead to an erroneous conclusion on the normality of the fetus. Levels are also raised in obstetric problems (threatened miscarriage, intrauterine growth restriction, perinatal death and antepartum haemorrhage) and some congenital abnormalities (exomphalos, nephrosis, Turner's syndrome, trisomy 13), but are depressed in trisomy 21 (Canick et al 2003). The introduction of more effective maternal serum markers and better-resolution fetal ultrasound has led to the diminished use of isolated AFP measurements.

KEY POINTS

1. Hormones are chemical messengers, classically distributed via the circulation, that elicit specific effects in target cells.
2. The three major types of hormones are peptides and the derivatives of amino acids and cholesterol.
3. Negative and positive feedback mechanisms operate to regulate hormone production.
4. Hormone action is mediated by binding to receptors and triggering intracellular responses.
5. The tissue distribution of the receptor determines where a hormone will exert its effect.
6. The two major subdivisions of hormone receptors are either cell surface or intracellular (usually nuclear).
7. Peptide hormones and catecholamines act on cell surface receptors.
8. Activation of cell surface receptors can generate fast responses in seconds or minutes.
9. Steroid and thyroid hormones act on intracellular, usually nuclear, receptors.
10. Activation of intracellular/nuclear receptors generates slower responses due to the need to produce protein from the expression of target genes.
11. Hormone potency is directly related to the length of time that the hormone–receptor complex occupies the nucleus.

12. Due to the amplification of hormone signals by the second messenger system, only 1% of cell receptors need to be occupied by the hormone for its action to be evident.
13. Downregulation by internalization of hormone receptors is a unique mechanism for limiting polypeptide hormone activity.
14. Agonists are substances that occupy cell receptors and stimulate natural physiological activity.
15. Antagonists are substances that occupy receptors without being internalized, hence blocking the cell function.
16. Endocrine investigations of ovarian function, with the sole exception of AMH, should be performed in the early follicular phase to guard against false results.
17. The choice of assay for specific measurement of the prevalent form or proportion in relation to the intact hormone in a particular clinical setting is critical, particularly for hCG and its variants.

Biosynthesis of steroid hormones

Anthony E. Michael and Robert Abayasekara

Chapter Contents			
INTRODUCTION	145	DEFECTS IN STEROID SYNTHESIS	152
PHYSIOLOGY	145	KEY POINTS	154
REGULATION OF STEROID SYNTHESIS	149		

Introduction

Steroid hormones are lipid molecules synthesized within the ovary, testis, placenta and adrenal cortex. Striking parallels exist in the organization of the biosynthetic pathways and the hormonal control of steroid production in each of these steroidogenic tissues. This chapter will outline the general principles of steroid hormone formation as regulated by trophic hormones, before considering detailed aspects of ovarian and adrenal biochemistry in health and disease. The chapter opens with a consideration of the general structures of steroid hormones, since relatively minor structural differences impact profoundly on the biological and clinical actions of each steroid hormone.

Physiology

The classification of steroid hormones

All steroid hormones are ultimately derived from the 27 carbon (C) substrate cholesterol and so share the same cyclohexaphenanthrene ring structure (Figures 11.1 and 11.2). Steroids are classified into five families dependent upon the number of carbon atoms and the chemical groups present at key carbon residues (Table 11.1). Those steroid hormones with 21 carbon atoms are collectively termed 'pregnenes', and this category of steroid hormones can be subdivided into three steroid families: progestins (e.g. progesterone), glucocorticoids (e.g. cortisol) and mineralocorticoids (e.g. aldosterone). While the progestins are secreted predominantly from the ovary, the glucocorticoids and mineralocorticoids are collectively termed 'corticosteroids', reflecting their origin in the cortex of the adrenal gland. The major structural difference between the three pregnene families is that while progestins possess a methyl group (CH₃) at position C21, both glucocorticoids and mineralocorticoids possess a C21 hydroxyl group (CH₂OH) (see Table 11.1 and Figure 11.2). Progestins can be metabolized

to generate 19 carbon steroids, termed 'androgens' [dehydroepiandrosterone (DHEA), androstenedione and testosterone], which are secreted from both the testis and the adrenal cortex. Within the ovary, androgens are usually metabolized to generate the oestrogens (e.g. oestradiol-17 β) with their characteristic 18 carbon structure (see Table 11.1 and Figure 11.2).

Within this classification scheme, there is a distinction to be made between Δ^5 and Δ^4 steroid hormones. Progestins and androgens of the Δ^5 series are characterized by possessing a hydroxyl group at position C3 and a C=C double bond between positions C5 and C6 in the steroid B-ring, as in cholesterol (Figure 11.1). In contrast, progestins and androgens of the Δ^4 series possess a ketone (C=O) at position C3 and have their C=C double bond between positions C4 and C5 in the A-ring of the steroid molecule (Figure 11.2). While this difference may seem a trivial biochemical detail, nothing could be further from the truth. The nature of the chemical group at position C3, together with the position of the C=C double bond, profoundly alters the conformation of the steroid molecule and, in so doing, influences the ability of the hormone to activate intracellular receptors. Hence, Δ^5 steroids, such as pregnenolone and DHEA, have low affinities for steroid receptors such that they can only exert limited biological actions. In contrast, the Δ^4 steroids, such as progesterone and testosterone, are potent activators of steroid receptors and so act as the dominant physiological hormones.

Origins and intracellular transport of cholesterol

An important issue in steroidogenesis is the provision of cholesterol, which can be derived from the following sources:

- circulating plasma lipoproteins;
- intracellular cholesteryl ester stores;
- cell membranes; and
- de-novo synthesis from acetate.

In both the ovary and adrenal cortex, plasma lipoproteins supply the majority of cholesterol for steroidogenesis and suppress intracellular cholesterol synthesis by inhibition of hydroxymethylglutaryl-coenzyme A reductase, the rate-determining enzyme for de-novo cholesterol synthesis.

Figure 11.1 The cyclohexenanthrene ring structure of cholesterol: the steroidogenic substrate.

Once inside the cell, cholesterol must be transported across the cytosol and into the mitochondria where the first and rate-determining reaction of steroid synthesis occurs: the catabolism of cholesterol to form pregnenolone (see below). The transport of cholesterol across the two mitochondrial membranes and interceding aqueous intermembrane space is now recognized as the true rate-limiting step for steroidogenesis, and so with this realization, it is this process which has been the focus of research into steroid biosynthesis over the past two decades. Although the understanding of the molecular mechanisms by which cholesterol passes from the outer leaflet of the outer mitochondrial membrane (OMM) to the inner leaflet of the inner mitochondrial membrane (IMM) is still far from complete, significant advances have been made over the past decade. In the mid 1990s, the importance of the steroidogenic acute regulatory (StAR) protein was first indicated when Clark and Stocco showed StAR to be a short half-life protein which is rapidly upregulated in steroidogenic cells following stimulation either by trophic hormones (e.g. gonadotrophins) or by the common second messenger, cyclic adenosine 3',5'-monophosphate (cAMP) (Stocco and Clark 1996). Analysis of the StAR peptide sequence suggested that this protein gets

Figure 11.2 Structures of the major physiological steroid in each steroid family.

Table 11.1 Definitive structural features of the five major families of steroid hormones

Steroid Family						
		Progestins	Glucocorticoids	Mineralocorticoids	Androgens	Oestrogens
No. of carbon atoms		21	21	21	19	18
Chemical group present at position	C21	CH ₃	CH ₂ OH	CH ₂ OH	Absent	Absent
	C18	CH ₃	CH ₃	H–C=O (aldehyde)	CH ₃	CH ₃
	C17	D-ring side chain	D-ring side chain	D-ring side chain	17 β -hydroxyl or ketone	17 β -hydroxyl or ketone
	C11	Nil	11 β -hydroxyl	11 β -hydroxyl		
	C3	Ketone or 3 β -hydroxyl	Ketone	Ketone	Ketone or 3 β -hydroxyl	Planar hydroxyl group attached to aromatic A-ring

imported from the cytosol into the IMM, and it was postulated that the StAR protein might simply bind and transport cholesterol across the aqueous intermembrane space during the course of that import. However, subsequent site-directed mutagenesis studies revealed that the StAR protein could still drive cholesterol flux for steroidogenesis even when it was modified to prevent mitochondrial import, and it is now accepted that the StAR protein can act at the OMM to drive cholesterol passage from the outer leaflet of the OMM to the inner leaflet of the IMM without itself trafficking into the mitochondria (Miller 2007). This steroidogenic action of the StAR protein does, however, require: (i) that the StAR protein be phosphorylated on key serine residues by the cAMP-dependent protein kinase A (PKA); and (ii) that the phosphorylated form of the StAR protein interacts with the 18 kDa translocator protein (TSPO) expressed in the OMM (Figure 11.3) (Hauet et al 2005, Miller 2007). The TSPO protein, which was originally described as a peripheral benzodiazepine receptor (PBR), is very highly expressed in the OMM of steroidogenic cells. Recent studies have revealed that rather than reliance on a single protein to drive mitochondrial cholesterol uptake for steroidogenesis, this pivotal rate-limiting step involves a complex of proteins which includes the StAR and TSPO proteins in association with PBR-associated protein-7 (PAP7). By virtue of its structural interactions with both the TSPO protein and the PKAR1 α regulatory subunit of PKA, PAP7 acts as a PKA-anchoring protein, localizing PKA to the OMM where it can phosphorylate the serine residues in the StAR protein to drive the StAR–TSPO interaction required to deliver cholesterol to the IMM for the first reaction in the steroidogenic pathway (Liu et al 2006, Miller 2007). While the StAR protein is not expressed in the placenta, this tissue does express a homologous protein, metastatic lymph node 64, which shares several functional and structural properties with the StAR protein, and is assumed to drive mitochondrial cholesterol uptake for placental steroidogenesis (Petrescu et al 2001).

Steroidogenic enzymes

Although the biochemical pathway of steroid hormone synthesis, summarized in Figure 11.4, can look like a bewildering railway map, the whole pathway becomes more

straightforward on recognizing that the eight major steroidogenic enzymes can all be classified into just two enzyme families (the cytochrome P450 enzymes and the hydroxysteroid dehydrogenases), each with definitive functions. The steroidogenic cytochrome P450 (CYP) enzymes are members of a larger superfamily of CYP oxidase enzymes. Each CYP enzyme catalyses a hydroxylation reaction by serving as the terminal electron acceptor in an electron transport pathway which transfers electrons from a pyridine nucleotide cofactor, nicotinamide adenine dinucleotide phosphate, via two sequential flavoproteins (ferredoxin reductase and ferredoxin) on to atomic oxygen (Miller 2008). This allows the atomic oxygen to be inserted, by the CYP enzyme, into a hydrocarbon (C–H) bond thus generating a polar hydroxyl group (C–O–H) which renders the substrate molecule more water soluble/hydrophilic. The non-steroidogenic CYP enzymes include those hepatic oxidase enzymes responsible for the inactivation and clearance of a wide range of drugs. Each of the CYP enzymes within the steroidogenic pathway has traditionally been referred to by a variety of names that reflect their ability to catalyse hydroxylation of a steroid substrate at a specific carbon position. However, following the completion of the human genome (HUGO) project, all steroidogenic CYP enzymes have been assigned new systematic names which relate to the CYP gene that encodes the enzyme protein (Table 11.2).

In addition to their characteristic hydroxylase activities, some steroidogenic CYP enzymes also catalyse lyase reactions. Specifically, the CYP11A (cytochrome P450 cholesterol side chain cleavage) and CYP17 (cytochrome P450 17 α -hydroxylase/C17,20-lyase) enzymes can each catalyse cleavage of the C–C bond weakened by the hydroxylation reactions. CYP11A acts in the IMM to catalyse the rate-limiting reaction in steroid synthesis: the conversion of cholesterol to pregnenolone. This crucial CYP enzyme hydroxylates two adjacent carbons (C20 and C22) in the D-ring side chain of cholesterol, facilitating cleavage between C20 and C22 to leave the Δ^5 21 carbon steroid, pregnenolone (Miller 2008). Similarly, CYP17 introduces a hydroxyl group at position C17 of either pregnenolone or progesterone, as a result of which the weakened C17–C20 bond breaks to generate either DHEA or androstenedione, respectively (Miller 2008) (see Figure 11.4). Other members of the CYP enzyme family

Figure 11.3 Cellular mechanisms for the acute and chronic steroidogenic responses to luteinizing hormone in a generalized ovarian cell. Open arrows indicate movement or metabolism; broken arrows indicate positive effects on downstream target proteins; see text for abbreviations.

simply catalyse introduction of oxygen to generate hydroxyl groups at specific carbon positions (see Table 11.2). The hydroxylations catalysed by CYP21 (21-hydroxylase) and CYP11B1 (11 β -hydroxylase) are pivotal in the formation of corticosteroids by the adrenal cortex (Miller 2008). The hydroxyl group generated at position C18 by CYP11B2 (aldosterone synthase) undergoes rapid oxidation to form an aldehyde group (Curnow et al 1991), hence giving rise to the name 'aldosterone' (see Figure 11.2). Finally, CYP19 (aromatase) is the most complex member of the steroidogenic CYP enzyme family, catalysing a series of reactions that convert C19 androgens (androstenedione and testosterone) to their C18 oestrogen metabolites (oestrone and oestradiol, respectively). In this reaction sequence, the C19 methyl group is lost and the ketone at position C3 is reduced to a hydroxyl group (Miller 2008). This liberates electrons which are invested in the A-ring of the steroid to generate the aromatic phenol ring, the hallmark of oestrogens (see Figure 11.2) and a prerequisite for activation of the oestrogen receptor.

The second family of steroidogenic enzymes comprises the hydroxysteroid dehydrogenase (HSD) enzymes encoded by *HSD* genes (Penning 1997, Miller 2008). (As with the CYP enzymes, the HSD enzymes have all been renamed following the completion of the HUGO project, such that the systematic names for the 3 β HSD and 17 β HSD isoenzymes

have changed to HSD3B and HSD17B, respectively.) All of the HSD enzymes catalyse the interconversion of a hydroxyl group with a ketone to influence the affinity of the steroid hormone for its intracellular receptors (Penning 1997). Each HSD enzyme is specified by a number and a Greek letter; the number denotes the position of the carbon atom at which the enzyme acts, and the Greek letter indicates the orientation of the OH group relative to the steroid molecule (where α and β indicate bonds below and above the plane of the molecule, respectively).

There are two HSD enzymes of significance in steroid hormone production. The two cloned HSD3B isoenzymes convert the 3 β -hydroxyl group of weak Δ^5 steroids to a ketone, and also catalyse movement of the C=C double bond to generate the corresponding Δ^4 steroid metabolite, thus increasing steroid potency (Penning 1997, Miller 2008). Hence, both the placental HSD3B1 enzyme and HSD3B2, expressed in the ovary, testis and adrenal gland, can convert weak Δ^5 steroids, such as pregnenolone and DHEA, to the active Δ^4 progestins and androgens, progesterone and androstenedione, respectively (see Figure 11.4). In contrast, the major HSD17B isoenzymes act at position C17 where they catalyse not oxidation but reduction, converting a ketone at C17 to a β -hydroxyl group. The significance of this reaction is attested to by the fact that androstenedione and oestrone (which have ketone groups

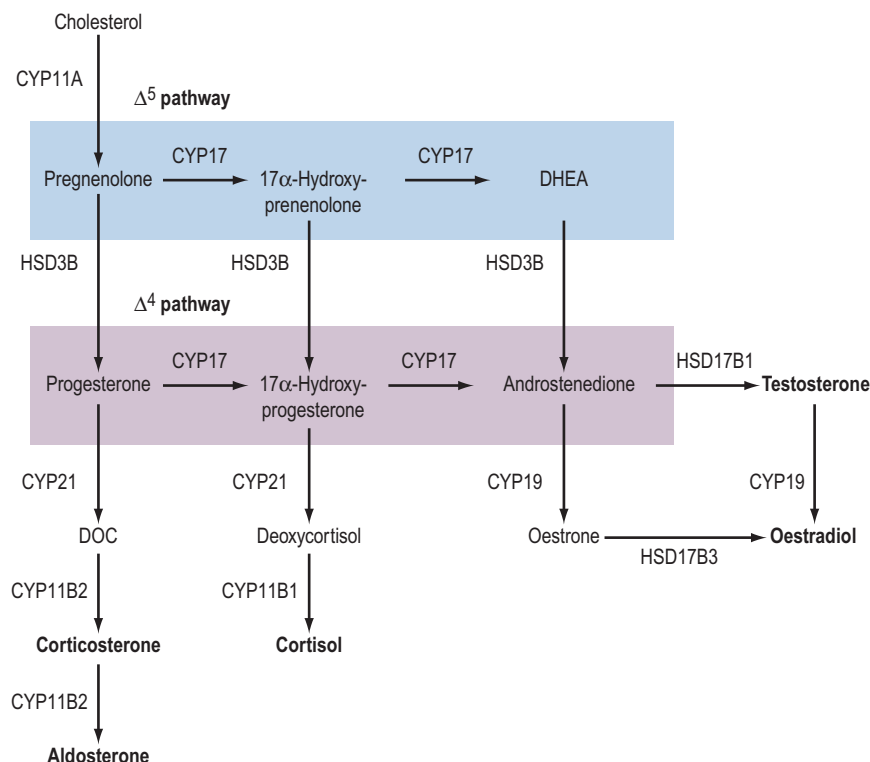

Figure 11.4 The general steroidogenic pathway. See text for abbreviations.

Table 11.2 The genetics and biochemistry of the steroidogenic cytochrome P450 (CYP) enzymes

Protein name			
Systematic name	Pseudonyms	Gene	Enzymatic reactions
CYP11A	P450 _{CSCC} / cholesterol side chain cleavage	<i>CYP11A</i>	Hydroxylation of C20 and C22 in cholesterol followed by cleavage of cholesterol side chain between C20 and C22 Converts cholesterol to pregnenolone
CYP11B1	P450 _{C11} / 11 β -hydroxylase	<i>CYP11B1</i>	Hydroxylation of C11 (in β orientation)
CYP11B2	P450 _{C18} / aldosterone synthase	<i>CYP11B2</i>	Hydroxylation of C18 followed by oxidation to generate an aldehyde group at C18
CYP17	P450 _{C17} / 17 α -hydroxylase; C17,20-lyase	<i>CYP17</i>	Hydroxylation of C17 (in α orientation) followed by cleavage of C17–C20 bond Converts progestins to androgens
CYP19	P450 _{AROM} / aromatase	<i>CYP19</i>	Generates an aromatic A-ring Converts androgens to oestrogens
CYP21	P450 _{C21} / 21-hydroxylase	<i>CYP21</i>	Hydroxylation of C21

at position C17) are relatively weak steroids, whereas their 17 β -hydroxy-metabolites, testosterone and oestradiol-17 β (see Figure 11.2), are the more potent androgen and oestrogen, respectively.

Regulation of Steroid Synthesis

In the ovary, testis and adrenal cortex, the synthesis of steroid hormones is regulated primarily by trophic hormones secreted from the anterior lobe of the pituitary gland, acting in conjunction with other endocrine, paracrine and auto-

crine modulators of steroidogenesis. The anterior pituitary hormones, being hydrophilic, have to act via cell surface receptors coupled to signal transduction pathways that increase the expression and activities of steroidogenic enzymes. While several second messengers are generated in response to trophic hormones, the steroidogenic responses to these proteins are mediated primarily through the generation of cAMP with activation of PKA. In the acute response to endocrine stimulation, activation of PKA phosphorylates: (i) cholesteryl ester hydrolase (increasing mobilization of cholesterol from intracellular lipid droplets); and (ii) the StAR protein (thus promoting mitochondrial uptake of

cholesterol for steroid biosynthesis) (Niswender 2002, Miller 2008). In addition, activation of the cAMP–PKA system rapidly upregulates expression of the StAR protein, apparently via the cAMP-response element modulator (CREM) protein interacting with a non-classical cAMP response element half-site in the promoter region of the *StAR* gene (Sugawara et al 2006). In the chronic steroidogenic response, PKA activates the cAMP response element binding (CREB) protein, and this transcription factor upregulates the expression of apolipoprotein B₁₀₀ [low-density lipoprotein (LDL)] receptors (Golos et al 1986) together with several of the steroidogenic CYP enzymes (Simpson et al 1990, Sewer et al 2007, Miller 2008) (see Figure 11.3).

Endocrine control of ovarian steroid synthesis

There are subtle differences in the endocrine control of oestradiol-17 β (hereafter, the -17 β has been omitted from the term ‘oestradiol’) and progesterone synthesis in:

- the follicular phase of the ovarian cycle (which corresponds to the proliferative phase of the menstrual cycle);
- the luteal phase of the ovarian cycle (which corresponds to the secretory phase of the menstrual cycle); and
- the corpus luteum (CL) of early pregnancy.

In the developing ovarian follicle, the synthesis of oestradiol is dependent upon both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) acting in concert (Hillier et al 1994). Within the theca cells, LH stimulates the synthesis of androstenedione. Until the mid-1990s, it was assumed that this weak androgen was metabolized to testosterone prior to secretion from the theca. However, molecular studies demonstrated that human theca cells do not express the HSD17B3 isoenzyme required to convert androstenedione to testosterone (Zhang et al 1996). Instead, androstenedione passes from the theca cell layer across the membrana propria into the follicular interior. Within the granulosa cells, CYP19 converts androstenedione to oestrone which is subsequently metabolized to oestradiol by the HSD17B1 enzyme. Hence, the synthesis of oestradiol in the ovarian follicle requires LH to stimulate androgen output from the theca cells, while FSH stimulates the expression of CYP19 in the granulosa cells (Hillier et al 1994) (Figure 11.5).

Clinical experience from assisted conception cycles has called into question this ‘two cell–two gonadotrophin model’ for follicular oestradiol biosynthesis. Prior to the development of highly purified and recombinant preparations of FSH, it had been assumed that the in-vivo oestradiol response to human menopausal gonadotrophin reflected the fact that this gonadotrophin exhibited both LH and FSH activities. However, even after effective suppression of pituitary gonadotrophin secretion using a gonadotrophin-releasing hormone (GnRH) analogue, follicular growth and oestradiol output can be stimulated by highly purified or recombinant FSH without the need for administration of exogenous LH (Schoot et al 1994). Although this finding prompted some researchers to question the need for LH to support ovarian oestradiol production, it has been contested that the low levels of endogenous LH remaining in patients following administration of a GnRH agonist/antagonist may

Figure 11.5 The two cell–two gonadotrophin model for follicular biosynthesis of oestradiol. See text for abbreviations.

still be adequate to stimulate synthesis of androgen precursor in the theca cells of ovarian follicles.

In the periovulatory phase of the ovarian cycle, oestradiol induces the expression of LH receptors within the luteinizing granulosa cells (Kessel et al 1985, Farookhi and Desjardins 1986). Hence, in the CL, both the granulosa- and theca-derived luteal cells express LH receptors (Rao et al 1978, Yeko et al 1989). Moreover, the luteinizing granulosa cells cease to express FSH receptors and so become unresponsive to FSH. In the luteal phase of the ovarian cycle, the majority of progesterone is synthesized within and secreted from the granulosa-derived cells of the CL under the endocrine stimulus of LH, acting via the cAMP second messenger system (Devoto et al 2002). Potential conversion of progesterone to androstenedione within the granulosa-derived luteal cells is restricted by the negligible expression of CYP17 (Sasano et al 1989). Molecular investigations have revealed that in the CL of women and non-human primates, oestradiol biosynthesis continues to require cooperation between two morphologically distinct cell populations. In the theca-derived luteal cells, cholesterol is converted to androstenedione by the sequential actions of CYP11A, CYP17 and HSD3B2. Androstenedione then diffuses into the neighbouring granulosa-derived luteal cells where it serves as a substrate for CYP19 in the synthesis of oestradiol (via oestrone) (Fisch et al 1989). Whereas expression of CYP19 in the follicular granulosa cells is reliant on FSH, expression of the same enzyme in luteinized granulosa cells is dependent upon LH (Devoto et al 2002). Hence, the CL employs a two cell–one gonadotrophin system for oestradiol biosynthesis, as opposed to the

two cell–two gonadotrophin system evident in the preovulatory follicle.

In the event of conception, the steroidogenic activity of the CL must be sustained until the luteo–placental shift, at which point placental steroidogenesis supersedes ovarian steroid production. The functional rescue of the CL, in a phenomenon referred to as the ‘maternal recognition of pregnancy’, relies on the fact that human chorionic gonadotrophin (hCG) can stimulate steroid synthesis in luteal cells via the same receptors as LH (Rao et al 1978, Jia et al 1991). Indeed, while hCG has a longer plasma half-life than LH, the glycoprotein structures that dictate receptor specificity are identical in LH and hCG, such that both hormones can bind the LH receptor with similar affinities (Jia et al 1991). In-vitro studies indicate that, on binding to the LH receptor in primate granulosa-derived luteal cells, hCG and LH are equipotent in increasing both intracellular cAMP levels and progesterone synthesis (Molskness et al 1991, Abayasekara et al 1993).

In addition to the gonadotrophins, other hormones, including growth hormone (GH) and insulin, have been implicated in the endocrine regulation of ovarian steroidogenesis, acting in synergy with the pituitary gonadotrophins (Franks 1998, Devoto et al 2002). Both GH and insulin activate receptor tyrosine kinases which phosphorylate different protein targets to those in the cAMP–PKA signal transduction cascade. This ability to operate through different cell signalling pathways may explain, at the cellular level, how insulin and GH can synergize with the gonadotrophins in stimulating ovarian steroidogenesis.

Glucocorticoids can also participate in the endocrine control of ovarian steroid biosynthesis. In general, these adrenal steroids antagonize the effects of gonadotrophins and suppress the activities of steroidogenic enzymes in ovarian cells, which may contribute to the dysregulation of ovarian steroid production in syndromes of adrenal hyperactivity (including chronic stress, anorexia nervosa and Cushing’s disease) (Michael and Cooke 1994).

Paracrine control of ovarian steroid synthesis

Within the ovary, a number of molecules exert paracrine/autocrine actions to modulate the steroidogenic response to the pituitary gonadotrophins. Recent interest has focused on such local actions of ovarian growth factors, some of which (e.g. vascular endothelial growth factor) influence ovarian activity (growth of ovarian follicles and development and maintenance of the CL) and steroid synthesis by mediating ovarian angiogenesis (Kaczmarek et al 2005). Others, such as the insulin-like growth factors (IGFs), act directly on follicular or luteal cells to synergize with LH or FSH in stimulating the activities of steroidogenic enzymes. For example, like insulin, IGFs I and II enhance the stimulation of theca cell androstenedione production by LH (Nahum et al 1995) and stimulate granulosa cell progesterone synthesis (Willis et al 1998). Members of the IGF family of growth factors provide the best example of how ovarian steroid production can be tightly controlled at the local level of the ovary. Not only are the paracrine/autocrine actions of IGFs dependent upon the local concentrations of each IGF and the appropriate plasma membrane receptors, but the effects of IGFs on ovarian steroidogenesis are further regulated by local concentrations

of IGF-binding proteins (IGF-BP1 to IGF-BP5 inclusive) (Giudice et al 1995).

Inhibin and activin, which were originally identified as major secretory products of the ovary and testis, are members of the transforming growth factor- β superfamily of growth factors (De Kretser and Robertson 1989, Hillier and Miro 1993). Within the developing ovarian follicle, inhibin and activin appear to act in concert to regulate the stimulation of androstenedione production in the theca cells and of CYP19 expression in the granulosa cells (Hsueh et al 1987, Hillier and Miro 1993).

Research in the 1990s clearly demonstrated that immune cells, particularly macrophages and lymphocytes, actively participate in the paracrine control of ovarian steroid synthesis (Chryssikopoulos 1997). At this juncture, it is relevant to note that cytokines released within the ovary from ovarian leucocytes can also modulate the effects of LH and FSH on ovarian steroidogenesis. For example, interleukin-1 β can inhibit LH-stimulated androgen synthesis in cultured theca cells (Hurwitz et al 1991).

Finally, prostaglandins synthesized either within the ovary or in the uterus (transported to the ovary by countercurrent exchange from the uterine vein to ovarian artery) can also affect ovarian steroidogenesis. In general, prostaglandin (PG) E₂ stimulates steroid biosynthesis (apparently via the same cAMP–PKA pathway as LH), whereas PGF_{2 α} can act in ovarian cells to antagonize LH action and thus inhibit progesterone synthesis in the CL (Michael et al 1994, Olofsson and Leung 1994). Indeed, it has been speculated that the local synthesis of PGF_{2 α} within the CL may induce the functional regression of this transient ovarian gland at the end of the non-fertile menstrual cycle (Michael et al 1994, Olofsson and Leung 1994).

Endocrine control of adrenal steroid synthesis

In the same way as steroid biosynthesis by the ovary depends on LH and FSH from the gonadotroph cells of the anterior pituitary gland, the synthesis of corticosteroids by the cells of the adrenal cortex is dependent upon adrenocorticotrophic hormone (ACTH) secreted from the pituitary corticotroph cells. This hydrophilic protein hormone binds to cell surface receptors on adrenocortical cells to activate the cAMP–PKA signal transduction pathway (Schimmer 1995). Through increases in intracellular cAMP concentrations, ACTH stimulates cholesterol uptake (via LDL receptors), increases both the expression and activities of the CYP and HSD enzymes required to synthesize the adrenal steroid hormones (Simpson et al 1990, Sewer et al 2007), and crucially upregulates expression of the StAR protein which can then be activated by PKA-mediated phosphorylation (as in the ovary).

The adrenal cortex comprises three functional zones: the zona reticularis, zona fasciculata and zona glomerulosa. Cells in each adrenocortical zone express a different complement of steroidogenic enzymes and so synthesize different steroid products. Adrenal zona reticularis cells do not express HSD3B2 and so their major secreted product is DHEA: a 19 carbon, Δ^5 steroid (i.e. weak androgen) which tends to be secreted as DHEA sulphate (Endoh et al 1996). The major product secreted from cells in the zona fasciculata of the adrenal cortex is the glucocorticoid cortisol which

exerts negative feedback at the hypothalamus and anterior pituitary gland to control subsequent endocrine input from ACTH. Hence, if the biosynthesis of cortisol is compromised or if a patient is glucocorticoid resistant (commonly due to a loss-of-function mutation in the glucocorticoid receptor), pituitary ACTH secretion becomes elevated and the ACTH induces increased proliferation of the adrenocortical cells; a condition termed 'congenital adrenal hyperplasia' (CAH; see below). The third and final zone of the adrenal cortex, the zona glomerulosa, expresses the CYP11B2 enzyme required for the conversion of corticosterone to aldosterone (Muller 1987). Hence, the major function of zona glomerulosa cells is the synthesis and secretion of the mineralocorticoid required to control sodium–potassium exchange in the kidney and colon. While the synthesis of DHEA(S) and cortisol is under the endocrine control of ACTH, the synthesis of aldosterone is regulated in a multifactorial manner, with the most important stimulus to secretion being altered electrolyte and fluid status (Muller 1987). A fall in plasma volume triggers an increase in the release of prorenin from the glomeruli of individual nephrons in the kidney. In the general circulation, the precursor protein prorenin is converted to the active enzyme renin which in turn metabolizes the plasma protein angiotensinogen to angiotensin I. Within the lungs, angiotensin-converting enzyme converts angiotensin I to angiotensin II and it is the latter peptide which acts at the zona glomerulosa to increase the synthesis of aldosterone. Acting via mineralocorticoid receptors in the distal segments of renal nephrons and in the colon, aldosterone stimulates the uptake of sodium ions in exchange for potassium ions. Since the net influx of sodium ions exceeds the efflux of potassium ions, water is reclaimed from the lumen of the nephron or colon, thus increasing plasma volume and hence blood pressure to close this homeostatic loop. As aldosterone increases the loss of potassium from the body, the synthesis of aldosterone in zona glomerulosa cells can also be stimulated directly by a rise in the plasma potassium concentration (Muller 1987).

Defects in Steroid Synthesis

Genital virilization/female pseudohermaphroditism

Virilization of the external female genitalia (see Chapter 13) usually reflects a pathological increase in androgen secretion from either the adrenal zona reticularis or the ovary. The severity of clinical presentation, ranging from clitoromegaly with labial hypertrophy to male external genitalia (usually with hypospadias), depends upon the source and age of onset of the elevation in the plasma androgen concentration (hyperandrogenaemia).

Congenital adrenal hyperplasia

Increased adrenal androgen output (adrenal hyperandrogenism) is a hallmark of the common forms of CAH and usually reflects loss-of-function mutations in CYP21 or CYP11B1 which prevent cells of the zona fasciculata from synthesizing cortisol (Figures 11.6 and 11.7). The conse-

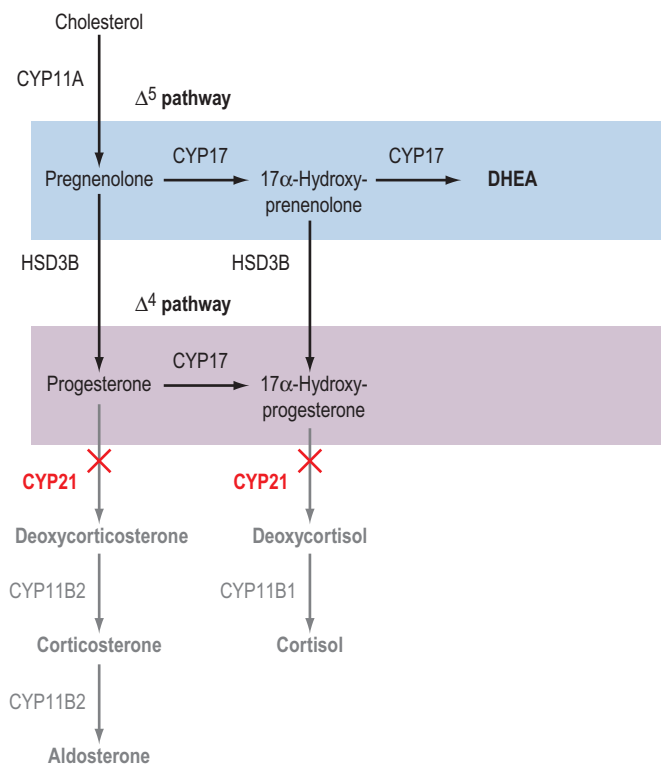

Figure 11.6 The adrenal steroidogenic pathway in 'salt-wasting' congenital adrenal hyperplasia; loss of function of CYP21. See text for abbreviations.

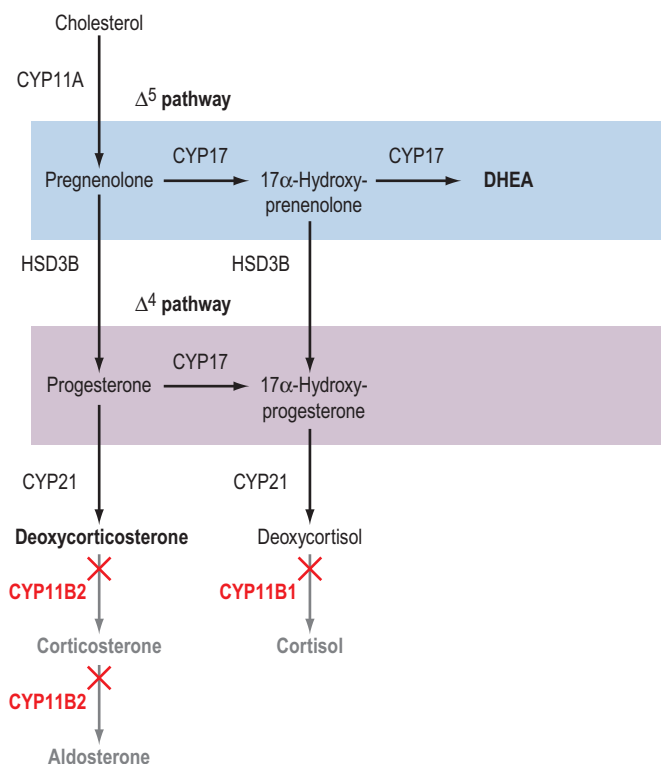

Figure 11.7 The adrenal steroidogenic pathway in 'salt-sparing' congenital adrenal hyperplasia; loss of function of CYP11B1. See text for abbreviations.

quent loss of negative feedback within the fetal hypothalamo–pituitary–adrenal axis causes an elevation in ACTH that stimulates adrenal hyperplasia with increased synthesis of DHEA in utero (White et al 1987). Although DHEA is only a weak androgen, this Δ^5 steroid can be metabolized to androstenedione and testosterone in peripheral tissue, such as subcutaneous adipose tissue. Within the genital skin fibroblasts, the sequential actions of the HSD3B, HSD17B and 5 α -reductase enzymes convert DHEA to 5 α -dihydrotestosterone (DHT) which causes virilization of the external genitalia. Under the action of DHT, the genital tubercle differentiates into a glans, the urethral folds fuse to form a phallus and the labioscrotal swellings fuse to form an empty scrotum (see Chapter 13). In addition to causing virilization of the external genitalia, adrenal hyperandrogenism will also manifest as development of male secondary sexual characteristics in a woman (see Chapter 26). Of these, the most notable tend to be male-pattern hair loss, hirsutism and increased body odour, symptoms commonly observed in women with polycystic ovary syndrome (PCOS) (see below and Chapter 18).

Although the effects of excessive DHEA production on the external genitalia and secondary sexual characteristics obviously affect a patient's future sexual identity and fertility, the other endocrine sequelae of CAH are of greater medical importance. In patients with complete loss of CYP21 activity (see Figure 11.6), the total absence of corticosteroids renders the patient unable to maintain normal glucose homeostasis (due to the loss of glucocorticoids) and to regulate sodium–potassium exchange in the kidney and colon (due to the loss of aldosterone). Hence, complete loss of CYP21 activity causes 'salt-wasting' CAH, alternatively referred to as 'simple virilizing' CAH (White et al 1987). In contrast, 'salt-sparing' CAH can result from either a partial loss of CYP21 activity or from a complete loss of CYP11B1 activity (White et al 1987, Nimkarn and New 2008) (see Figure 11.7). In either event, the absence of glucocorticoids presents as hypoglycaemia with depleted hepatic glycogen stores. However, in salt-sparing CAH, deoxycorticosterone (DOC), a weak mineralocorticoid, is able to exert some control over renal and colonic ion balance. Indeed, because the synthesis of DOC is outside the control of the renin–angiotensin axis, this steroid tends to hyperstimulate sodium resorption and loss of potassium, and because water movement follows the flux of sodium ions, the elevation of DOC usually results in the hypervolaemic syndrome of 'malignant hypertension' in patients with salt-sparing CAH.

Ovarian hyperandrogenism

Prior to puberty, the normal ovary synthesizes very low levels of steroid hormones. At and after puberty, LH stimulates androgen production by the follicular theca cells while FSH stimulates the metabolism of those androgens to oestrogens in the neighbouring granulosa cells. If this delicate biochemical system becomes disturbed, increased androgen production from the ovary (ovarian hyperandrogenism) can result in enlargement of the clitoris plus internal and external labia. As ovarian hyperandrogenism is usually (although not always) reliant on LH, virilization of the female external genitalia (as opposed to female pseudohermaphroditism) and the development of male secondary sexual characteris-

tics tend to be reported after the pubertal increase in gonadotrophin concentrations. An obvious exception to this generalization is observed in women presenting with hypergonadotrophic hypergonadism.

Essentially, there are three potential causes of ovarian hyperandrogenism:

- a disturbance in the LH:FSH ratio;
- stimulation of ovarian androgen synthesis by an agent other than a gonadotrophin; and
- decreased CYP19 activity.

In accordance with the two cell–two gonadotrophin model of oestradiol biosynthesis, alterations to the LH:FSH ratio, as reported in patients with PCOS and in menopausal women, can cause an imbalance between LH-stimulated androgen synthesis in the theca cells and the FSH-dependent aromatization of androstenedione in the granulosa cells. When LH is inappropriately elevated and/or FSH is suppressed, the synthesis of androstenedione in the theca can exceed the capacity of CYP19 to metabolize the thecal androgen substrate, such that there is net secretion of androgen from the ovary into the general circulation.

As noted earlier in this chapter, insulin and IGFs can also stimulate thecal androgen production, significantly enhancing the steroidogenic response of theca cells to LH (Nahum et al 1995). By definition, PCOS is characterized by elevated plasma concentrations of insulin (hyperinsulinaemia) accompanied by clinical signs of hyperandrogenism (see Chapter 18). A number of studies have indicated that the hyperinsulinaemia reported in women with PCOS reflects resistance to the cellular actions of insulin in peripheral tissues (muscle and adipose tissue) (Dunaif et al 1989). However, the ability of insulin to stimulate ovarian steroidogenesis appears to be preserved in PCOS patients (Ben-Shlomo 2003), such that in PCOS, the elevated concentrations of insulin may act in concert with LH to stimulate excess ovarian androgen production.

Mutations in the CYP19 gene

A final mechanism for disturbing the delicate biochemical balance between the theca and granulosa cell compartments of the ovarian follicle is to decrease the capacity of the granulosa cells to metabolize thecal androstenedione substrate. The simplest mechanism to explain such a distortion in the steroidogenic pathway would be a complete loss-of-function mutation in the *CYP19* gene that encodes the aromatase enzyme. Due to the requirements for oestradiol and oestriol in pregnancy, fetuses affected by complete loss of function in *CYP19* are usually miscarried. However, a few patients with severely limited CYP19 activity have been reported. In such patients, failure of the granulosa cells to metabolize any androgen precursor results in profound ovarian hyperandrogenism with progressive clitoromegaly and accelerated linear growth (MacGillivray et al 1998). Interestingly, affected girls do not show the usual cessation of linear growth at puberty, despite having plasma testosterone concentrations far in excess of the reference range for normal adolescent boys. These patients have revealed the crucial role for the CYP19 enzyme in the fusion of the epiphyses in the long bones; in both sexes; closure of the epiphyseal plates requires testosterone to be aromatized within the

bone to oestradiol, such that women with defective CYP19 activity require administration of exogenous oestrogen to halt their linear growth (MacGillivray et al 1998).

Although mutations in CYP19 are rare, there are other disease states in which the capacity of granulosa cells to aromatize androgens is limited to the extent that ovarian hyperandrogenism ensues. For example, loss-of-function mutations in the FSH receptor, which have been associated with hypergonadotrophic ovarian dysgenesis, can prevent

FSH from upregulating CYP19 expression in the granulosa cells despite a normal plasma LH:FSH ratio (Tapanainen et al 1998). Alternatively, glucocorticoids can inhibit the expression and activity of CYP19 in cultured granulosa cells (Hsueh and Erickson 1978, Fitzpatrick and Richards 1991), an observation that explains, in part, the association between adrenal hyperactivity and dysregulation of ovarian steroid synthesis in conditions such as anorexia nervosa and other chronic stress syndromes.

KEY POINTS

1. Steroid hormones are all synthesized from cholesterol, derived predominantly from plasma lipoproteins.
2. Each steroid hormone can be classified into one of five families, the names of which reflect their biological functions.
3. The biosynthesis of steroid hormones involves just two families of steroidogenic enzymes: CYP enzymes and HSD enzymes.
4. Steroid synthesis is controlled by trophic hormones which increase the expression and activities of steroidogenic enzymes and the StAR protein.
5. The endocrine actions of the gonadotrophins and ACTH are moderated by paracrine agents arising within the ovary and adrenal cortex, respectively.
6. In addition to compromising fertility, defects in the synthesis of ovarian and adrenal steroid hormones can dramatically alter the development of the external genitalia and the secondary sexual characteristics of a patient.

Introduction

Expedited by completion of the draft version of the Human Genome Project in 2001 (Lander et al 2001, Venter et al 2001), the last decade has witnessed unprecedented advances in experimental methods in an ambitious effort to link genomics with whole-organism physiology and pathophysiology. The genome amongst individuals is 99.9% homologous, with diversity of function generated through postgenomic regulation at the mRNA and protein level. Detailed analysis of the human genome shows it to consist of approximately 3.1 billion base pairs (Little 2005). Of the genes, approximately 24,000, far fewer than the number expected, encode proteins with phenotypic diversity generated by multiple splice variants. It is estimated that over 800 additional genes are transcribed into small microRNAs (miRNA), although significantly more encode non-coding RNA (Little 2005). Clearly, the draft sequence has provided tantalising insight into the mysterious organization and complexity of the human genome that will be gradually unravelled for years to come.

New developments and refinement of large-scale, high-throughput investigations, often referred to as 'omic technologies', seem set to transform medicine. This is likely to be achieved through improved prediction, detection, diagnosis and treatment of disease, as well as better monitoring of the healthy state. There have also been crucial advances in the generation of new insight into our understanding of the regulation of global gene expression. Specifically, the central dogma which describes forward flow of information of DNA–RNA–protein, initially overturned by the discovery of the enzyme reverse transcriptase (which converts RNA to DNA), is matched by exciting developments in the field of RNA biology. The context of these developments and application of this new technology to gynaecology is presented herein with key examples from the literature.

Global Screening and Analysis

Traditionally, pursuit of scientific enquiry has been hypothesis-driven, which by its nature deconstructs complex biological systems into manageable 'bite-sized' studies with a very specific research question. In our wider quest to understand systems biology and networks, a reductionist approach is ill suited to investigating the integrative nature of whole-organism physiology, specifically the interactions between genes, protein and function. Given the immense volume of sequence data generated by the Human Genome Project, an escalation in research targeted towards population-based, high-throughput screening of gene expression has since been observed. The emphasis on networks, rapid advances in -omic technologies and high-dimensional biology has produced unparalleled insight into the relationships between the genome, transcriptome, proteome and, more recently, the metabolome. These innovative approaches have also necessitated unprecedented dependence on the discipline of bioinformatics. Table 12.1 lists key websites that are the backbone of such investigations requiring information on gene and protein sequences, gene annotation, sequence homology, microarray analysis etc. Many of these are freely available, with two of the most comprehensive and popular sources of sequence information being the National Center for Biotechnological Information (NCBI) and Ensembl.

Microarray technology

Gene sequence data in isolation provide little information on protein function. 'Functional genomics', the term used to describe the relationship between genes and physiological mechanisms on a global rather than individual basis, has evolved to probe these interactions. In particular, pioneering research using genechip technology enabling

simultaneous global gene expression of thousand of genes (Skena et al 1995, Brown and Botstein 1999) has been at the forefront of functional genomics, and is the mainstay of high-throughput assays. It is a powerful means of identifying subsets of genes that are either up- or down-regulated in a particular research scenario (Duggan et al 1999, Hegde et al 2000). Specifically, gene expression may be compared: (1) in different tissues/cells, (2) under developmental regulation (fetal versus adult) and on ageing, (3) in normal and disease states, and (4) in response to, for example, drug treatments, environmental cues etc.

Practical Aspects and Analysis

Microarrays

The success of DNA microarray technology exploits the complementarity of Watson–Crick base pairing that underlies hybridization of sample cDNA to either short oligonucleotide or cDNA sequences immobilized in a grid-like fashion on a solid substrate (Duggan et al 1999, Hegde et al 2000). Typically, a glass slide, nylon membrane or

silicon wafer is the preferred format, although bead-based arrays are also available. For cDNA arrays, probe sequences principally derive from the IMAGE (Integrated Molecular Analysis of Genomes and their Expression) clone library arising from the Human Genome Project. These arrays include known genes whose function is as yet unknown, and expressed sequence tags whose full sequence and function are yet to be determined. High-density oligonucleotide arrays, such as those provided by Affymetrix, may be fabricated *in situ* by solid-phase chemical synthesis combined with photolithography. The sequences on Affymetric chips derive from 'refseq' — the definitive version of the gene sequence — contained within the NCBI suite of programs (Table 12.1). Currently, the latest arrays from Affymetrix offer unparalleled whole-genome analysis with over 700,000 probes representing over 28,000 human genes on a single array. Despite the diversity of microarrays available, some may not include the gene of interest to the specific research group, leading to the loss of key information in the study of gene pathways. An alternative strategy is to manufacture tailored arrays that include a smaller set of known genes of interest.

Once a research question has been formulated, the basic steps in a DNA microarray experiment, illustrated in Figure 12.1, commence with extraction and reverse transcription of total RNA or mRNA into cDNA from samples under investigation. Sample cDNA is then labelled either with radioactive or fluorescent probes and hybridized to the array. The main advantage of radioactive over fluorescent labelling is the enhanced sensitivity of the former. A currently popular approach involves differential labelling of test and control sample cDNA with the fluorophores Cy3 and Cy5. Following stringent washing to remove non-specific binding, image analysis of the emitted signal is performed either by quantitative phosphorimaging of radioactively labelled samples or by powerful laser scanning of fluorescence. These raw data are subsequently processed to generate scatter plots that offer a quick and easy means of surveying unaltered, up- or downregulated genes. A gene expression matrix, consisting of data organized in rows and columns reflecting the output of each individual gene in a particular sample, allows the data to be ranked and probabilities determined in order to identify individual fold changes in gene expression as a result of a biological effect. Typically, more than a two-fold change in transcript expression is taken to indicate biological relevance.

Inherent in these methods is the technical variation arising from a number of sources including RNA quality, variable probe labelling, high background etc. Distinguishing between real experimental changes and those due to technical variation is achieved by some form of normalization designed to remove bias and to ensure that the results obtained are an accurate depiction of a true biological effect. Normalization generally requires subtraction of background intensity from the signal of each gene. Other forms of normalization include comparison of gene expression against a known set of reference (housekeeping) genes included on the array that demonstrate constant expression irrespective of tissue type and conditions. The Human Gene Expression database (Table 12.1) is a useful source of information of such genes expressed in a variety of tissues.

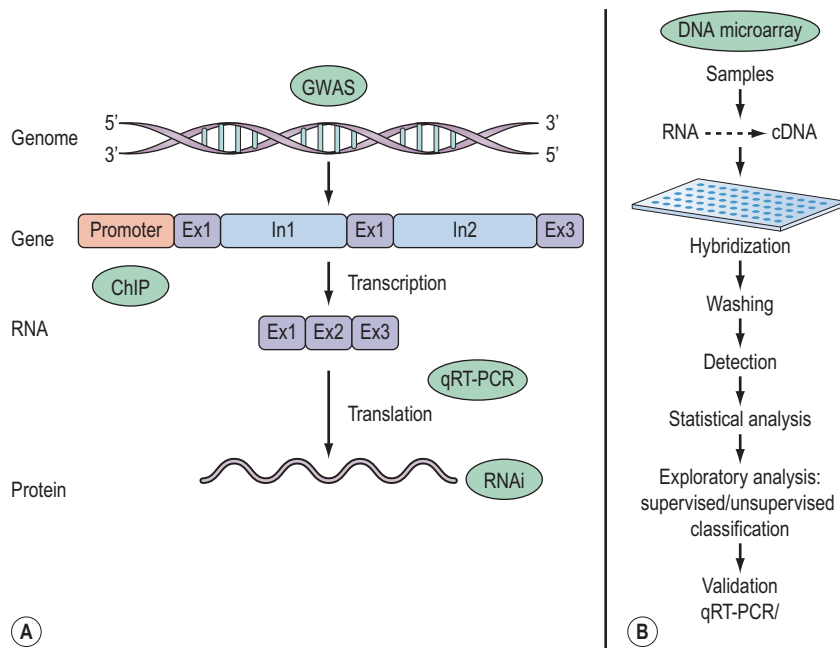

Figure 12.1 (A) Schematic illustration showing the transition from genome to protein. The structure of a gene contains introns (In) and exons (Ex). Techniques used in investigating aspects of molecular function are highlighted in the context of the entity targeted. Thus, GWAS for genome-wide association studies, ChIP (chromatin immunoprecipitation) for studying gene–protein interactions through the promoter region, and qRT-PCR (quantitative reverse transcriptase polymerase chain reaction) for transcript analysis using cDNA reverse transcribed from RNA and RNA interference for post-transcriptional silencing. (B) The steps involved in carrying out a DNA microarray experiment.

Statistical analysis

Once microarray data have been collected, standard methods used to determine real as opposed to chance changes in gene expression levels may be analysed using parametric or non-parametric techniques. In the former case, the *t*-test uses a measure of within-treatment error that results in finding genes that only have a large change in expression levels relative to the within-treatment variance. This is usually resolved by undertaking a suitable number of experiments to reduce the variance, but is not so easy with array data where experiments are expensive.

An alternative approach is to use fold change, in which the within-treatment variance is ignored. The problem with this is that variances do matter and vary between genes and treatments. Moreover, fold change may stem from an initially low level of expression, possibly reducing the biological significance of the change. A method of improving the power of the *t*-test is to use a Bayesian statistical approach that uses prior knowledge of within-treatment measurement (Baldi et al 1998). In the case of arrays, this is achieved by assuming that genes with similar expression levels have similar measurement errors (Baldi and Long 2001). In addition, the data are not viewed in isolation but in the context of known biological interactions.

Given the caveats that apply to the use of the *t*-test for statistical analysis of array data, an alternative method used to derive probability values that has been applied to microarray data is the use of permutation tests. Unlike the *t*-test, permutation tests do not require data to be normally distributed nor variances to be equal, and are therefore more likely to detect real changes in expression. Tusher et al (2001) have developed a method that uses permutation tests known as ‘Significance Analysis of Microarrays’ (SAM), where each gene is assigned a score taking into account its expression and standard deviation. The uptake of the SAM method has been greatly facilitated by the availability of an Excel plug-in. It also provides information on the false discovery rate,

which corrects for false-positive results in order to eliminate random changes in gene expression.

Exploratory data analysis and data models

Since the aim of most microarray experiments is to identify differential gene expression compared with a control sample/condition, some means of organizing genes into meaningful subsets forms part of exploratory analysis. For example, a comparison between normal and endometriotic tissue may unveil changes in multiple genes involved in inflammation or cell adhesion. Similarly, treating a cell line with steroids may lead to a downregulation of genes encoding inflammatory cytokines. Exploratory analysis investigates such relationships using unsupervised or supervised classification to identify patterns of gene expression based on similarity measurements, yet providing little or no information on the statistical significance of the findings. Supervised classification is distinct from unsupervised methods since it involves making prior assumptions about the data sets but may introduce bias (Shipp et al 2002).

Broadly speaking, unsupervised methods that include cluster analysis (Kerr and Churchill 2007) or principal components analysis (Hilsenbeck et al 1999) identify groups of genes that change and cluster them into cognate groups. One of the shortfalls of this approach is that genes that do show changes with expression but have no perceived function may be overlooked. This is more so when one considers that it is likely that several genes may be implicated in a physiological response. A further problem is in identifying the best model within which to place the individual gene expression changes. Genes may be clustered using hierarchical clustering (Eisen et al 1998), two-way clustering (Alon et al 1999), k-mean clustering, principal components analysis (Tavazoie et al 1999) and self-organizing maps (Tamayo et al 1999). It is also preferable to determine the validity of applying particular clustering algorithms to one’s data by carrying out bootstrap or jack knife analysis (Reimers 2005). Detailed

mathematical arguments relating to supervised and unsupervised methods are beyond the scope of this chapter; readers are referred to the preceding references and the following sources for further information: Reimers (2005), D'Haeseleer (2005), Thalamuthu et al (2006) and Kerr et al (2008).

Limitations of microarrays

Although the use of microarrays has dramatically altered the field of molecular biology, it is no easy task to compare data across groups and arrays due to the variation in arrays used, normalization protocols employed, and statistical analyses and exploratory models applied. In an attempt to reach a consensus on sharing and storing array data, Brazma et al (2001) have launched Minimum Information About A Microarray Experiment (MIAME) as a mechanism for recording detailed relevant information on the execution and analysis of array experiments made publicly available for use by independent researchers.

Despite their undoubted utility in the laboratory, the limitations of DNA microarray methods are listed below.

- They do not detect mRNA but cDNA. The relationship between expression of mRNA and cDNA is complex and governed by several factors. Thus, cDNA levels may not mirror mRNA expression precisely.
- There is currently no method that allows reliable measurement of RNA.
- Arrays provide information on changes in hybridization signals for thousands of genes that cannot be performed in large replicates.
- Sources of error may arise from poor sample, RNA quality, probe labelling or background noise.
- It is not practicable to assess the identity of the DNA on the array, and errors relating to gene annotation, although rare, do occur.
- Having performed such studies at significant cost and effort, comparing microarray data is difficult and some agreement on standardizing experimental design in order to make valid comparisons has been proposed.

DNA microarrays remain a popular experimental tool, such that the technology has now extended to array-based global analysis of miRNAs, DNA methylation, genome-wide scanning and proteins. A further modification of this method for analysing histone modifications and gene-promoter sequence binding is based on chromatin immunoprecipitation (ChIP), which utilizes formaldehyde fixation to provide a snapshot of protein–DNA molecular interactions *in situ* (Wathelet et al 1998). This method has advantages over traditional *in-vitro* methods used to study transcription factors (i.e. electrophoretic mobility shift assays) and gene reporter studies that employ synthetic segments of promoter DNA that do not form chromatin with a structure reflective of that in native chromosomal DNA. ChIP-on-ChIP is an array-based method that allows mass screening of gene promoters involved in transcription and repression of genes (Collas 2009), and is a valuable addition to the armoury employed in studying gene regulation.

Validation of Microarray Data

All biological processes are ultimately regulated by the repertoire of genes that are expressed in a cell at a given time.

The cellular response to physiological and pathophysiological stimuli will also depend on changes in this profile. Array hybridization (and other techniques) is designed to identify the transcripts in a cell and to estimate their relative abundance. Thus, the array itself is a form of quantitative assessment. However, since array studies are often performed on relatively few specimens, additional quantitative methods are frequently required to investigate small numbers of genes in multiple samples. This is often termed 'array verification'. As array technology and the associated data-processing methods become more robust, use of this verification will decrease. Nonetheless, some verification is prudent and is most readily achieved using a polymerase chain reaction (PCR)-based approach.

Quantitative polymerase chain reaction

The sensitivity of the PCR has been instrumental in the elucidation of gene expression profiles at a cell and tissue level. Most readers will be familiar with the basis of the PCR which uses Taq polymerase, a thermostable enzyme isolated from the bacterium *Thermus aquaticus*, to exponentially amplify gene expression. Taq DNA polymerase has intrinsic 5'–3' exonuclease activity, optimal at approximately 72°C, and amplifies at a rate of 30–70 bases per second. The technique uses either template DNA or RNA from various sources (ex-vivo tissue biopsies, cell lines, blood, cloned DNA, microbial DNA) to compare expression of product (amplicon) under varied experimental conditions as described earlier. Quantitative PCR (qPCR) has rapidly supplanted conventional 'endpoint' PCR (Higuchi et al 1992, Wittwer et al 1997, Kubista et al 2006). It represents a major refinement where assay throughput has been greatly improved with 96- or 384-well plate formats, fluorescence detection and the commercial availability of ready prepared 'master mixes' that only require the addition of cDNA to amplify the relevant gene. The process of amplification essentially involves continual cycling between denaturation of double-stranded DNA to generate two single-template strands that undergo annealing to target primers, followed by strand extension and a consequent increase in product copy number.

Unlike DNA-PCR, which is relatively reliable and easily quantifiable, quantitative reverse transcriptase PCR (qRT-PCR), which requires the conversion of total RNA to cDNA with the enzyme reverse transcriptase (RT step), is a recognized error-prone reaction. RNA is significantly more labile than DNA, requiring careful handling. The crucial RT step is the source of much of the inaccuracy in quantification of gene expression due to inherent variability in, for example, the rate of reverse transcription and the choice of either oligo (dT)-18 or random hexamers for the priming of cDNA. The former produces a more accurate transcript profile which reflects the mRNA gene pool of the sample, with transcription requiring full-length, unfragmented, high-quality mRNA. Random hexamers prime cDNA from multiple points along the same transcript, thereby producing possibly more than one cDNA transcript per original target sequence, and also amplify ribosomal RNA. The choice of whether to use random hexamers, oligo-dT primers or a combination of both is a matter for the investigator. All RT reactions should be run in parallel with 'no RT' controls, that are duplicates of the original RNA reaction but with RT omitted

in order to determine possible contamination with genomic DNA that would lead to false-positive results.

The heterogeneous nature of tissue samples is an additional complication, and it is advisable that, wherever possible, laser capture microdissection should be utilized in order to determine gene expression in specific cell types which will be more meaningful in interpreting association of gene expression with phenotype. Fortunately, this is relatively straightforward using techniques such as confocal immunofluorescence, immunohistochemistry and in-situ hybridization to determine a site of expression of the target protein or gene.

Primer design is a critical step in a PCR reaction. The current trend, however, is to purchase primers using software, in many cases provided by companies with expertise in qPCR. At a cost, these companies will also design primers on request, supplied as part of an assay kit where all reagents are optimized for the primers. The main disadvantage in ordering primers via this route is the lack of disclosure on information regarding the primer sequence, thus making it difficult to know exactly where the primer is annealing. Many freely available primer design tools are available on the internet.

Fluorescence chemistry in quantitative reverse transcriptase polymerase chain reaction

The two most widely used forms of fluorescence detection for qPCR are as follows.

- DNA-binding dyes: SYBR green was the first available fluorescent probe to be used in qPCR and qRT-PCR as it is easily incorporated into a normal reaction mix. It acts by intercalating with double-stranded DNA, thus generating approximately 1000-fold increased fluorescence intensity compared with unbound dye. Shortcomings of this method include its indiscriminate binding to any form of double-stranded DNA,

including both the amplicon as well as primer-dimers. However, melt-curve analysis that enables distinction between specific and non-specific amplification based on knowledge of the desired amplicon is easily performed as part of the reaction. Figure 12.2 illustrates qRT-PCR undertaken using human endometrial cDNA and SYBR green chemistry.

- Hydrolysis probes using Taqman chemistry, the most popular of the fluorescence approaches, are based on the incorporation of an oligonucleotide probe which hybridizes to the DNA circumscribed by the two PCR primers. The probe is typically labelled with a fluorophore at its 5' end and a quencher at the 3' end. The 5'–3' exonuclease activity of Taq polymerase as it progresses along the template digests a portion of the probe, sequentially removing each fluorescent dye molecule, finally achieving spatial separation from the dye at the other end of the probe. When these dyes are close together, their fluorescence is quenched [by fluorescence resonance energy transfer (FRET)]. Upon separation, this effect is lost and fluorescence is emitted. Since the product from one cycle is the template for the next, the amount of probe hybridized and therefore digested during each cycle increases. This leads to an increase in the emitted fluorescence which is proportional to the amount of initial template present. The Taqman probe method does not lend itself to melt-curve analysis. More sensitive FRET-based detection methods are available that do permit melt-curve analysis, but their use is limited by the expense in using this chemistry.

Data analysis and interpretation in quantitative polymerase chain reaction

Quantification of the qRT-PCR assay is most accurately determined during the exponential phase of the reaction when amplification products are being generated at a steady

Figure 12.2 Quantitative reverse transcriptase polymerase chain reaction (PCR) of the adhesion molecule E-cadherin in human endometrium using the SYBR® green method. All three samples are characterized by a C_t of 17. Inset illustrates a melt curve showing a single peak produced during the amplification, indicating the formation of a specific amplicon. CF RFU, curve fit relative fluorescence units.

optimum rate, approximately 10–20 cycles into the reaction. The software creates an amplification plot with the measured fluorescence signal plotted against the cycle number. The single most important readout of the qRT-PCR is the C_t and this is the first fluorescence signal that occurs above the threshold limit for fluorescence detection. Differences in C_t values are used to calculate the relative abundance of template between samples, as the C_t value is directly proportional to the amount of template at the start. A crucial factor in qPCR is the amplification efficiency, calculated from the slope of the calibration curve (see below) which should be close to 100% (Higuchi et al 1992).

Quantification in qPCR is carried out by one of two methods: absolute or relative. Both methods have advantages and disadvantages, and the decision regarding which one to use is one of personal choice.

Absolute quantification

This is a method by which known concentrations of nucleic acids are used to generate a standard curve from which unknown mRNA expression levels for target genes may be determined. For the method, known concentrations of cDNA or copy number are used in a calibration curve to create a standard curve with C_t plotted against log concentration or copy number cDNA. The data in Figure 12.2 illustrate an amplification curve showing E-cadherin expression in human endometrium.

Relative quantification

Also known as the delta delta C_t ($\Delta\Delta C_t$) method, this uses a simpler approach in that there is no requirement for a standard curve and all quantification is based on C_t values expressed relative to a housekeeping or reference gene (Pfaffl 2001). However, this method is only effective if the reference gene of choice is constant in expression between samples or treatment. The amplification efficiencies of both the target and reference genes should be equal. Despite this, it remains a widely used method.

Normalization

As with microarray data, normalization is an essential step in qRT-PCR and is typically performed in relation to a reference gene. As reference genes are known to vary in many different cell types under various conditions, it is good practice to probe samples for more than one single reference gene (Vandesompele et al 2002). A new standard for determining an appropriate reference gene is derived from the GeNorm programme, which takes actual C_t values from a sample for a number of tested reference genes that are stated in the paper and uses an algorithm to assign an M value to determine the most appropriate stable reference gene from those tested (Vandesompele et al 2002).

It is essential that qPCR and RT-qPCR studies are reported accurately. The varied format currently adopted by researchers does not lend itself to critical appraisal and does not permit comparisons to be made easily. As with microarrays, guidelines on the minimum information for publication of quantitative real-time PCR experiments have been developed (Bustin et al 2009). Researchers undertaking qPCR/

qRT-PCR are encouraged to comply with the recommendations made in this article.

Genome-Wide Association Studies

Mapping of single nucleotide polymorphisms and links to complex diseases

The abundance of sequence data produced by the Human Genome Project has made possible the use of microarrays in elucidating genomic variations that predict susceptibility to common diseases that include diabetes and cardiovascular disease (Wellcome Trust Case Control Consortium 2007). Thus, genome-wide association studies (GWAS) utilize large-scale, high-throughput methods to perform unbiased parallel genomic analysis of an unprecedented number of biological samples. The expectation is that this approach will be incorporated into personalized medicine or pharmacogenomics where responses to treatment will be predicated on an individual's genotype.

GWAS is based on the principle that predisposition to common diseases is attributable to a small number of genetic variations, and that large-scale screening of populations or families will identify sequence patterns predictive of disease (Nica and Dermizakis 2008). Most complex diseases are a consequence of a composite, non-Mendelian inheritance of multiple genes. The most common source of genetic variation within the human genome is the single nucleotide polymorphism (SNP), where the replacement of one nucleotide with another at a related locus potentially alters the downstream protein product encoded. SNPs, approximately 12 million of which reside within the human genome, are the preferred genetic markers due to their abundance, occurring approximately once every 1000 base pairs. Access to the HapMap database — a repository cataloguing the genetic variation in ethnically distinct populations and their link to health and disease (Frazer et al 2007) — has been instrumental in the launch of GWAS studies. Not all SNPs cause disease (Stranger and Dermizakis 2006) and, interestingly, experimental evidence indicates that SNPs account for only a small proportion of the phenotypic variance, implying association with other non-genetic factors, particularly gene-environment interactions.

The availability of arrays that contain millions of cDNA fragments allows an individual's genotype to be queried for up to 2 million known genetic variants. The design of GWAS may take the form of:

- a case-control study, in which individuals with disease are compared with a disease-free control group;
- a cohort design where a large number of individuals are recruited from a similar sample then categorized according to genetic variants; or
- the trio design, which attempts to survey an afflicted individual and his/her parents. This latter approach is best suited to Mendelian inheritance of disease (Pearson and Manolio 2008).

Pertinent to female health, the Womens' Genome Health Study, a full-cohort prospective GWAS, was commenced recently (Ridker et al 2008). The goal of this project is to

produce a fully searchable database of SNPs for women in order to identify polymorphism patterns that predict disease in otherwise healthy women. The Women's Genome Health Study will use the same study population of well-characterized healthy women initially recruited to the Women's Health Study. These women have already undergone 12 years of monitoring for major health events that include, amongst several others, cardiovascular disease, cancer, diabetes and osteoporosis. Significantly, this study has collated an extensive amount of epidemiological information along with baseline blood samples for several disease biomarkers and DNA for genotyping, as well as dietary and behavioural data that will allow gene-environment and gene-gene interactions to be examined.

Post-Transcriptional Repression and Regulation

The role of microRNA and short, interfering RNA

Probably the single most important discovery in cell biology in recent years relates to that of small non-coding RNA molecules, specifically short, interfering RNA (siRNA) and miRNA (Figure 12.3). The landmark paper describing RNA interference (RNAi), where Fire et al (1998) used double-stranded RNA to silence gene expression in *Caenorhabditis elegans*, has caused a paradigm shift in our interpretation of post-transcriptional regulation. It is estimated that over half of the genes encoding proteins in the human are likely to be regulated by miRNAs, providing a compelling case for further research in this field.

Both miRNA and siRNA are produced endogenously in the nucleus, although siRNA was initially thought to have a solely exogenous origin, deriving principally from viruses. siRNA has since been demonstrated in native cells where it has been termed 'endo-siRNA'. Interestingly, biogenesis of both siRNA and miRNA proceeds by a similar mechanism, described below, which evokes silencing in association with

the Argonaute (Ago) superfamily of proteins (Meister et al 2005, Tomari and Zamore 2005).

miRNAs, in their fully-processed mature form, are short (18–24), single-stranded segments of RNA that bind to the 3' UTR region of mRNA to induce transcriptional silencing (Carthew and Sontheimer 2009). They are produced in the nucleus from DNA by the action of RNA polymerase II to generate a long (hundreds to thousands of nucleotides), double-stranded precursor, primary RNA or pri-miRNA. The latter is spliced in the nucleus into pre-miRNA (70 nucleotides in length) by the enzyme 'Drosha' (Lee et al 2002), then exported to the cytoplasm by an accessory protein, exportin 5. Further processing of pre-miRNA by the enzyme 'Dicer' yields a miRNA duplex of approximately 22 nucleotides and a two-nucleotide overhang at the 3' end (Yi et al 2003, Gregory et al 2005). Entry of this duplex into the RNA-induced silencing complex induces the association of one strand (the guide strand) with Ago where it is unwound and post-transcriptional repression of target mRNA ensues (see Figure 12.2). The other 'passenger' strand is degraded. It is interesting that perfect complementary base pairing between miRNA-mRNA results in degradation of the target mRNA, while a slight mismatch of base pairing induces silencing and translational repression (Tomari and Zamore 2005). Whilst the specific mechanisms that determine whether target mRNA is degraded or repressed remain an active area of research, imperfect base pairing has evolved as an ingenious mechanism that explains the multiplicity of targets for miRNA clusters. It should be borne in mind that some miRNA species only have one target.

Apart from their roles in development and stem cell differentiation, miRNAs appear to play a key role in both oncogenesis and tumour suppression. miRNAs involved in oncogenesis involve the miR-17-92 cluster implicated in a mouse model of lymphoma (He et al 2005). Intriguingly, circulating miRNAs have been detected in blood and serum of cancer patients (Lawrie 2008), thus presenting an opportunity to harness miRNAs for diagnostic, prognostic and therapeutic purposes in the management of a wide range of malignancies.

Figure 12.3 Post-transcriptional regulation of microRNA. Pri-miRNA, produced from the action of RNA polymerase II on the miRNA gene, is cleaved by the enzyme Drosha into a pre-miRNA transcript ~70 nucleotides long. Pre-miRNA exits the nucleus after associating with exportin 5, a nuclear transporter. In the cytosol, a ribonuclease III known as Dicer processes the pre-miRNA into a ~22 nucleotide duplex. The mature strand of the duplex then preferentially enters the RNA-induced silencing complex (RISC) to attach to newly formed RNA to elicit silencing. The shaded part of the figure illustrates the conventional sequence whereby mRNA is translated into protein.

The emergence of RNAi (Fire et al 1998) and the early success of siRNA in achieving targeted protein knockdown has overcome several obstacles. In practical applications, siRNA has been replaced with short hairpin RNA (shRNA), where the two individual strands of shRNA are linked by a short loop sequence of approximately eight nucleotides. shRNA mimics this short hairpin loop found in most native RNA species, therefore replicating function more faithfully than siRNA. Although siRNA technology holds great promise, one of the problems with its use was the observation that binding of the guide strand to large numbers of genes resulted in altered expression of a host of miRNA species; a phenomenon known as 'off-targeting'. While this has been largely overcome through improved design of siRNA, another problem surfaced with the finding that shRNA-expressing vectors were dose-dependently linked to increased mortality in experimental animals, indicating overloading of the siRNA pathway. In addition, this study also challenged the notion that siRNA species lack immunogenicity since an immune response that involved Toll-like receptors — the pattern recognition family of Toll-like receptors — could be elicited (Grimm 2009). Despite these concerns, the experimental and potential therapeutic advantages of siRNAs provide a compelling case for their translation to the clinical arena.

Applications to Reproductive Biology

Significant milestones in reproductive biology that have transformed lifestyles include the development of the oral contraceptive pill, hormone replacement therapy and in-vitro fertilization. The power of gene cloning, as exemplified by the case of 'Dolly the sheep', has helped to launch the field of regenerative medicine and stem cell biology. Science has made many other, less well-known breakthroughs that have contributed to improving female health. Despite this, effective pharmacological therapies for the treatment of endometriosis, infertility, recurrent miscarriage and polycystic ovary syndrome (PCOS) remain elusive. Indeed, our understanding of the main female reproductive disorders is limited due to a paucity of research funding compared with diseases such as diabetes, cardiovascular disease and cancer. Microarrays in conjunction with new developments in our understanding of transcriptional regulation may elucidate temporal, tissue- and cell-specific gene signatures. Moreover, given the similarities between PCOS and diabetes, a GWAS approach to this condition may identify common genetic variations that might inform or predict development of PCOS. High-throughput technologies will undoubtedly provide new approaches to knowledge, diagnosis and therapeutics in all areas of reproductive biology.

Implantation/fertility

One of the most intractable problems facing reproductive medicine is failed implantation, whether this arises in natural cycles or in assisted reproduction. Transcript profiling studies, summarized in a recent review (Sherwin et al 2006), have sought to define endometrial function and receptivity. More recently, functional genomics has provided new information on molecular phenotyping of normo-

ovulatory women (Talbi et al 2006). The authors convincingly demonstrated that microarray methods are as effective as histological methods in dating the endometrium. By using k-means clustering, a unique molecular signature associated with early proliferative, early secretory, mid-secretory and late secretory phase endometrium was also identified. Whilst studies of miRNA in the female reproductive tract are in their infancy, deletion of 'Dicer', an enzyme involved in miRNA processing, causes multiple reproductive defects that include reduced ovulation rates, loss of embryo integrity and oviductal cysts (Luense et al 2009). Investigations in humans on the role of 'Dicer' may uncover a common function of this enzyme in fertility. Given the ubiquity of RNA silencing, it is likely that developments in understanding failed implantation and subfertility will involve further forays into the field of miRNAs.

Endometriosis

The surgical and medical treatment of endometriosis remains a major area of clinical interest. Current medical strategies seek to induce a pseudomenopause or pseudopregnancy. Newer approaches include the use of aromatase inhibitors, gonadotrophin-releasing hormone antagonists, selective oestrogen modulators and antiprogesterins. Alternatively, it might be possible to find new response genes or miRNAs that are differentially expressed in endometriotic lesions compared with eutopic endometrium. A recent investigation showed differential expression of 22 miRNAs in ectopic versus eutopic endometrium (Ohlsson Teague et al 2009). The target pathways appear to involve the *c-jun* and protein kinase B signalling pathways. On this basis, new therapeutic strategies targeting these cascades or the miRNAs implicated offer new direction in the future treatment of endometriosis.

Ovarian cancer

Ovarian epithelial tumours are of several histological subtypes, broadly being divided into serous and mucinous and by the degree of differentiation. A downregulation of miR-21 and several of the let-7 family of miRNAs in ovarian tumours has been reported, while miR-221 expression was raised (Dahiya et al 2008). A recent investigation has also identified that the mRNA for key enzymes 'Drosha' and 'Dicer' that catalyse miRNA biogenesis is reduced by 51% and 60%, respectively, in invasive ovarian cancer. Furthermore, high levels of 'Dicer' and 'Drosha' correlated with increased patient survival (Merritt et al 2008). A study of six types of cancer including ovarian demonstrated that miRNA profiling in tiny volumes (<1 ml) of serum could clearly distinguish between normal donors and cancer patients (Lodes et al 2009). These findings raise the prospect of using less-invasive serum-based assays in ovarian cancer detection and progression.

Conclusions

Whilst the discovery of genes not previously thought to be involved in basic processes of reproduction is clearly important, it is still a long way to understanding their function and

even further to developing new treatments. An additional opportunity provided by the new technology is to approach the question of biological function from a slightly different angle. Seldom does one gene exert an overarching effect on cellular function. Rather, the cell acts in response to many genes. Similarly with a tissue, the gene profile of a whole tissue will reflect cell type and the overall state of the many different cells that constitute the tissue. An alternative way of viewing these abundant data is to try to ask questions about the whole data set. In this system, complex patterns of gene expression are sought without making prior judgments about which genes are important or are most likely to be differentially expressed.

It is difficult to imagine new developments in technology that exceed the enormous power and potential of microarrays. However, we are poised at the threshold of a new era of next generation or deep sequencing methods. These platforms offer unparalleled supremacy which will, for the first time, enable comprehensive, integrative interrogation of sequences directly allied to -omics. Deep sequencing sur-

passes even the power of the newer arrays, while the sheer volume of data produced will require considerably enhanced statistical and computing power.

Microarray techniques have developed beyond cDNA to offer arrays for proteins, phosphoproteins, miRNAs, DNA methylation etc. which will allow a comprehensive interrogation of physiology at several levels. miRNAs have emerged as key players in cancer, with specific miRNAs and miRNA clusters contributing to tumorigenesis and cancer progression. There has been increased research activity into epigenetic mechanisms; the study of gene interactions with the environment. The advent of new knowledge and development of powerful new high-throughput methods is set to dramatically alter the face of medicine, and the era of pharmacogenomics is beckoning. Our hope is that the treatment of diseases that have afflicted women for years will improve significantly as a consequence of the great strides to be expected through RNAi, GWAS and deep sequencing for the improvement of female health globally.

KEY POINTS

1. Mapping of the human genome will define the finite nature of the human condition.
2. The introduction of DNA gene expression microarrays has led scientists to study genome-wide expression profiles, but creates its own difficulties in interpretation.
3. Such techniques allow the study of changes in expression of individual genes as a result of a biological effect. However, in many instances, interactions of several genes are required to induce a protein interaction, or one gene may affect more than one cellular function.
4. High-density arrays initially utilizing large numbers of cDNA fragments or synthesized oligonucleotide arrays have been modified for array-based investigations of miRNAs, DNA methylation, gene promoters, and metabolomic and proteomic expression.
5. The PCR is widely used in order to validate findings from microarrays as it can amplify the signal of interest and make detection of change more apparent. qPCR is the gold standard for DNA array verification.
6. The discovery of small, non-coding miRNAs and siRNAs along with the application of RNAi herald a new era investigating post-transcriptional regulation.
7. GWAS will provide unparalleled insight into genetic variation underpinning complex diseases
8. Deep sequencing platforms with unsurpassed power to date will generate new knowledge on the interactions between genes, RNA and proteins.
9. 'omic' technologies provide powerful and comprehensive tools for understanding reproductive biology. Careful application of the methodology will lead to new insights into disease causation and, potentially, new treatment options.

INTERSEX DISORDERS	169	KEY POINTS	179
46XY DISORDERS OF SEXUAL DEVELOPMENT	172		

Introduction

Sexual differentiation and its control are fundamental to the continuation of most species. The understanding of this process has advanced greatly in recent years, but before abnormalities of these disorders can be discussed, an understanding of normal sexual development is important. At fertilization, the haploid gametes unite and the conceptus contains 46 chromosomes with 22 autosomes derived from each of the gametes (i.e. sperm and ovum). The ovum donates one X chromosome and the sperm donates either one X or one Y chromosome; the axiom of mammalian reproduction is that a 46XX embryo will differentiate into a female, and a 46XY embryo becomes a male. It is, however, the presence or absence of the Y chromosome which determines whether the undifferentiated gonad becomes a testis or an ovary, and therefore the development of a male or female of the species.

Normal Embryological Development of the Reproductive System

Although chromosomal sex is determined at the time of fertilization, gonadal sex results from the differentiation of the indifferent undifferentiated gonad which becomes either a testis or an ovary. This begins during the fifth week of embryological development; at this time, an area of coelomic epithelium develops on the medial aspect of the urogenital ridge, and proliferation leads to the establishment of the gonadal ridge. Epithelial cords then grow into the mesenchyme (primary sex cords), and the gonad now possesses an outer cortex and an inner medulla. In XY individuals, the medulla becomes the testis and the cortex regresses. In embryos with an XX complement, the cortex differentiates to become an ovary and the medulla regresses. The primor-

dial germ cells develop by the fourth week in the endodermal cells of the yolk sac, and during the fifth week, they migrate along the dorsal mesentery of the hindgut to the gonadal ridges, eventually becoming incorporated into the mesenchyme and the primary sex cords by the end of the sixth week (Figure 13.1).

Development of the testis

The primary sex cords become concentrated on the medulla of the gonad and proliferate, and their ends anastomose to form the rete testis. The sex cords become isolated by the development of a capsule called the 'tunica albuginea' and the developing sex cords become the seminiferous tubules. Mesenchyme grows between the tubes to separate them (Leydig cells). The seminiferous tubules are composed of two layers of cells: supporting cells (Sertoli cells) derived from the germinal epithelium, and spermatogonia derived from the primordial germ cells (Figure 13.1).

Development of the ovary

The development of the ovary is much slower than that of the testis, and the ovary is not evident until the 10th week. Now, the primary sex cords regress and finally disappear. Around 12 weeks, secondary sex cords arise from the germinal epithelium, and the primordial germ cells become incorporated into these cortical cords. At 16 weeks, these cortical cords break up to form isolated groups of cells called 'primordial follicles'; each cell contains an oogonium derived from a primordial germ cell, surrounded by follicular cells arising from the cortical cords. These oogonia undergo rapid mitosis to increase the numbers to thousands of germ cells called 'primary oocytes'. Each oocyte is surrounded by a layer of follicular cells, the structure being called a 'primary follicle'. The surrounding mesenchyme becomes the stroma.

Figure 13.1 Normal gonadal differentiation.

Genetic control of gonadal development (Figure 13.2)

The pathway which controls the genetic interaction which transforms intermediate mesoderm to the bipotential gonad is beginning to be understood. It is now possible to identify with certainty two genes that are associated with this process. These two genes are Wilms' tumour gene (*WT1*) and *FTZ1*. *WT1* has been found on chromosome 11, p13 and regulates DNA transcriptase (Hastie 1994, Dong et al 1997). *FTZ1* produces steroidogenic factor 1 (*SF-1*), and this has been found to be required for differentiation to the bipotential gonad (Wilhelm et al 2007).

As the presence of a Y chromosome is essential for testicular differentiation, the localization of testicular-determining factor (TDF) which was localized at the short arm of the Y chromosome using cloning and DNA sequencing tech-

niques, and the gene determining TDF was sequenced and designated *SRY* (sex-determining region Y gene) (Guellaen et al 1984, Behlke et al 1993). The second gene which is involved in the differentiation of the testis is known as *SOX9*, and this gene coexists with the *SRY* gene in its homeobox and is a regulator of DNA transcription. *SOX9* gene expression is increased in male gonadal differentiation and decreased in female gonadal differentiation. *SOX9* has also recently been shown to be a regulator of type II collagen which is involved in the formation of cartilage (Lefebvre et al 1997). The *DAX1* gene is responsible for development of the receptor on the surface of the undifferentiated gonad, which allows *SRY* and *SOX9* to differentiate the gonad to become a testis. Following the development of Leydig cells and Sertoli cells, *SF-1* is involved in the control of steroid hydroxylases, and P450 aromatase causes an increase in the synthesis of testosterone and a reduction in the conversion

45X — ovarian dysgenesis
- 47XXX syndrome — subfertile female

of androgens to oestrogens, leading to a contribution to testicular regulation (Ogata 2008). In combination with ST1, it is also responsible for Sertoli cells producing anti-Müllerian hormone. Following differentiation, Leydig cells produce insulin-like 3 (*INSL3*) gene, expression of which leads to testicular descent and shortening of the gubernaculum (Foresta and Ferlin 2004).

The genes involved in ovarian differentiation are much more difficult to define, although *DAX1* expression continues during ovarian differentiation. Therefore, it is suggested that *DAX1* antagonizes the actions of the *SRY* gene (Swain et al 1998).

Sex chromosome anomalies

Variations may occur in the number or the structure of chromosomes in a mosaic or a non-mosaic form. The non-mosaic forms are summarized in Box 13.1.

Aneuploidy

Aneuploidy may result from the non-disjunction of either mitotic division or in either parent or in an early cleavage of the zygote. Some are more common in the offspring of older

women (e.g. 47XX and 47XXY), and the non-disjunction is presumed to arise mainly in the maternal meiosis. The occurrence of 45X does not seem to be related to maternal age.

Although there are a wide range of clinical effects, some generalizations can be made:

- if there is a Y chromosome, the phenotype is usually male;
- if the number of sex chromosomes increases beyond three, there is a strong tendency to some degree of mental retardation;
- an additional Y chromosome tends to increase height;
- provided there is at least one Y chromosome, one or more extra chromosomes result in hypogonadism; and
- in each somatic cell, only one X chromosome is active; others are inactivated.

Klinefelter's syndrome and XYY syndrome occur in approximately one in 700 newborn males, the clinical features of which are well recognized. These include hypogonadism, infertility, increased risk of testicular cancer, gynaecomastia, increased risk of male breast cancer, and sparse facial and body hair.

Turner's syndrome results from a chromosome constitution of a missing X chromosome. The overall incidence of this condition is approximately one in 2500 female births, but many of these have a mosaic pattern with a chromosome constitution of 46XX/45X. Small stature is invariable and gonadal failure is usual. There are other somatic features such as web neck, low hairline, cubitus valgus, pigmented naevi and cardiovascular anomalies, particularly coarctation of the aorta. These individuals do not have systematic impairment of the intellect, but they have some impairment of spatial ability.

XXX syndrome arises in approximately one in 1200 live female births, and no consistent clinical syndrome is associated with this.

Mosaicism

This is more common for sex chromosomes than for autosomes and arises when two cell lines arise from a single zygote due to non-disjunction in an early mitosis. The most common are 46XX and 46XY accompanied by a 45X cell line. The clinical effects are wide ranging depending on the balance of the mosaicism.

Structural abnormalities of X chromosomes

Apart from the number of X chromosomes in mosaicism, there are a number of possible variations within the X chromosome in the female. The X chromosome carries a large number of genes, not all of which have been delineated but some of which are responsible for metabolic and development disorders, and the gene map for the X chromosome is constantly being updated. If there is one normal X chromosome and the other is abnormal, inactivation of the abnormal X chromosome usually occurs in the somatic cells and this tends to diminish the effect of the abnormality, except in the ovary. Although only one X chromosome is sufficient for early ovarian development, germ cell maintenance requires several loci on the second X chromosome and on autosomes (Figure 13.3) (Simpson 1999).

Figure 13.3 Diagram of banded chromatid of X chromosome indicating the main numerical locations, on the left. On the right, phenotypic effects of some sites affected by deletions or variations are noted (based on data in Therman and Susman 1993 and Simpson 1999).

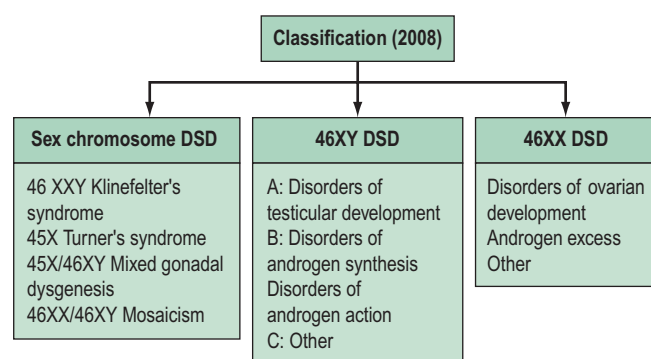

Figure 13.4 2008 classification of inter-sex disorders. DSD, disorders of sexual development.

Intersex Disorders

Intersex disorders are best classified into three groups (see Figure 13.4). This classification was suggested by Hughes (2008) as a new simple classification which includes all disorders of intersex.

Female (46XX) disorders of sexual development

Definition

This group of disorders comprises conditions in which masculinization of the external genitalia occurs in patients with a normal 46XX karyotype. The degree of masculinization is variable, ranging from mild clitoromegaly to complete fusion of the labial folds with a penile urethra.

Pathophysiology

The abnormalities occur when a female fetus is exposed to elevated levels of androgens. As the differentiation of the external genitalia to male or female depends on the conversion of testosterone to dihydrotestosterone (DHT) in the tissues of the cloaca, the presence of DHT leads to male-type development. If the female fetus is exposed to low levels of androgen, partial masculinization may occur, leading to ambiguous genitalia; however, if the levels are sufficiently high, complete male external genital development may occur, although the testes are naturally absent. If androgen exposure is delayed until after 12 weeks, virilization is limited to clitoral enlargement with no effect on the already differentiated labia. Androgens have no effect on internal sexual development, and therefore the ovaries, uterus and upper vagina are normally formed and functional.

Aetiology

The causes of androgenization are due to excessive androgens either:

- arising in a fetus (e.g. congenital adrenal hyperplasia);
- arising in the mother (e.g. androgen-secreting tumour); or
- ingested by the mother (e.g. progestogens, danazol).

There are also cases which are associated with other congenital abnormalities or which are idiopathic.

Congenital adrenal hyperplasia

Pathophysiology

This is the most common cause of female pseudohermaphroditism and is an autosomal-recessive disorder resulting in enzyme deficiency in the biosynthesis of cortisol in the adrenal gland. Cortisol production occurs in the zona fasciculata and zona reticularis (Figure 13.5), and is controlled by adrenocorticotrophic hormone (ACTH) secreted by the pituitary gland. Adrenal androgen production occurs in the same area and is influenced by ACTH. A deficiency in any enzyme in the pathway results in decreased production of cortisol with resultant elevated levels of ACTH. This leads to increased steroid production by the adrenal reticularis and consequent hyperplasia. The stimulation by ACTH elevates the levels of circulating androgens, and this results in virilization of the female fetus.

There are three adrenal enzyme deficiencies which result in masculinization: 21-hydroxylase, 11-hydroxylase and 3 β -dehydrogenase deficiency.

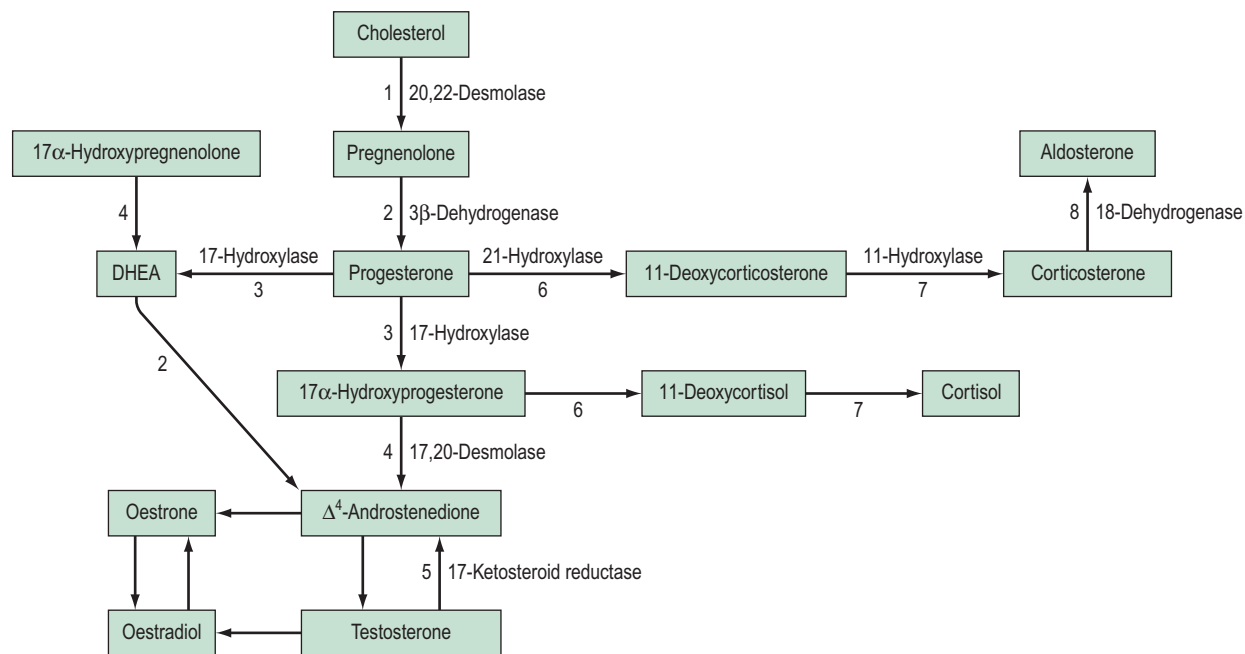

Figure 13.5 Adrenal synthesis of steroids.

21-Hydroxylase deficiency

This accounts for 90% of all cases of congenital adrenal hyperplasia. The deficiency results in an increase in progesterone and 17 α -hydroxyprogesterone, and this substrate is therefore converted to androstenedione and subsequently to testosterone. Failure of 21-hydroxylase to convert progesterone to 11-deoxycorticosterone may result in aldosterone deficiency; this occurs in approximately two-thirds of cases and is the so-called 'salt-losing' type of congenital adrenal hyperplasia.

Aetiology

Deficiency of 21-hydroxylase is an autosomal-recessive disorder. The link between human leukocyte antigen (HLA) type and 21-hydroxylase deficiency was established by Dupont et al (1977), and this allowed mapping of the gene which was located on the short arm of chromosome 6. It is located between the HLA-B and HLA-DR loci, and subgroups of HLA-B have been closely linked to congenital adrenal hyperplasia type: HLA-BW47 is linked to salt-losing congenital adrenal hyperplasia and HLA-BW51 is linked to the simple virilizing form. Studies by Donohoue et al (1986) have shown that there are two 21-hydroxylase genes: *21-OHA* and *21-OHB*. Only one is active (*21-OHB*) and they both lie between the fourth components of complement C4A and C4B. A variety of mutations have been reported, including gene deletions of *21-OHB*, gene conversions and point mutations.

Epidemiology

The incidence of 21-hydroxylase deficiency is between one in 5000 and one in 15,000, based on neonatal screening programmes (Cacciari et al 1983), although a higher incidence (one in 700) has been reported in specific populations of Eskimos (Pang et al 1982). The incidence of the non-

classic form of the disease, when androgenization fails to appear before late childhood or puberty, is much more common; approximately one in 300 in the White population and one in 30 in European Jews (Pang et al 1988).

Presentation

Affected females are born with an enlarged clitoris, fused labioscrotal folds and a urogenital sinus which may become a phallic urethra. There is often great variation in the degree of masculinization of the external genitalia; this is classified according to Prader (1958).

The internal genitalia develop normally as they are not influenced by androgens.

In salt-losing congenital adrenal hyperplasia, the infants develop dehydration, hypotension and hyponatraemia between 7 and 28 days of age, known as a 'salt-losing crisis'. Non-salt-losing congenital adrenal hyperplasia tends to cause less severe masculinization than the salt-losing type. In general, all children born with ambiguous genitalia, including cryptorchidism and hypospadias, should be screened for congenital adrenal hyperplasia. Without treatment, severe salt-losing disease is fatal.

When an infant is born with ambiguous genitalia, the management of the parents is very important. It is helpful to reassure them that the infant is healthy and that there is a developmental anomaly of the genitalia. If the initial examination of the child fails to identify palpable gonads, it is most likely that the child is female and the parents should be informed as such; the likelihood of congenital adrenal hyperplasia may be raised. The diagnosis must then be made with as much haste as possible to alleviate parental anxiety.

Investigation

The initial investigations are karyotyping, pelvic ultrasound and endocrine studies. The karyotype may be performed on a sample of cord blood or on a venous sample, and rapid

results obtained. Pelvic ultrasound to discover the presence of a uterus and vagina will confirm the diagnosis. The specific diagnosis is made by measuring 17 α -hydroxyprogesterone in serum, although a 24-h urinary estimate of 17-ketosteroids will also confirm the diagnosis.

Treatment

This is divided into four parts.

Acute salt-losing crisis

This involves correcting the electrolyte imbalance and replacing the cortisol deficiency with deoxycorticosterone acetate (DOCA), 1 mg/24 h. For the majority of cases, 9 α -fludrocortisol is used at a dose of 0.1–0.2 mg/day added to the oral feed, and the dosage of DOCA or fludrocortisol is adjusted against the electrolyte levels.

Long-term cortisol replacement therapy

Although previous reports suggested that mineralocorticoid therapy could be discontinued after infancy (Newns 1974), more recent data suggest that it is essential to continue therapy for life (Hughes et al 1979).

Surgical correction

Once the sex of rearing has been established as female, some attempt to feminize the genitalia may be made, usually within the first 18 months of life. If the clitoris is enlarged, a reduction clitoridectomy can be performed and the perineal region modified (Edmonds 1989). There are major surgical problems associated with severe virilization in congenital adrenal hyperplasia. The urogenital sinus has been formed by labial fold fusion and the folds are usually thin, but may be thick with associated narrowing of the lower vagina, especially in salt-losers. If the labial folds are thin, division by a simple posterior incision may be performed around 3 or 4 years of age. However, thick perineal tissue should be left until after puberty, and no attempt at surgery should be made until the girl is physically and mentally sexually mature. The operation, when it is performed, involves a flap vaginoplasty with a pedicle graft of labia used to recreate the vagina. Alternatively, a Williams vaginoplasty may be used.

Mulaikal et al (1987) reviewed the fertility rates in 80 women with 21-hydroxylase deficiency; of 25 with the simple form who attempted pregnancy, 15 were successful, whereas only one of the salt-losers who tried to become pregnant succeeded. There is no doubt that a major reason for the failure of the salt-losing group is the disappointing results of surgery and subsequent lack of adequate sexual function.

Psychological support

As the child grows, long-term psychological guidance and support will be required for the parents initially and then the child.

Prenatal diagnosis

If the parents are heterozygous carriers of 21-hydroxylase deficiency, the fetus has a one in four chance of being affected. Thus, prenatal diagnosis is important, either by amniocentesis to measure levels of 17-hydroxyprogesterone in amniotic fluid, HLA typing of amniotic cells, or chorionic villus sampling and the use of specific DNA probes. Once

the diagnosis has been made, the option is available to treat the pregnant woman with oral dexamethasone, which crosses the placenta and suppresses the secretion of ACTH and thus the circulating androgen levels.

11-Hydroxylase deficiency

This is the hypertensive form of congenital adrenal hyperplasia which accounts for approximately 5–8% of all cases (Zachmann et al 1983). The absence of 11-hydroxylase leads to elevated levels of 11-deoxycorticosterone (DOC), and although this means a decreased amount of aldosterone, DOC has salt-retaining properties, leading to hypertension. Androstenedione levels are also elevated and this can result in ambiguous genitalia.

The diagnosis is made by measuring elevated levels of urinary 17-hydroxycorticosteroids and raised serum androstenedione. Treatment is similar to 21-hydroxylase deficiency, with glucocorticoid replacement therapy.

The genetics, however, are rather different. There is no HLA association with 11-hydroxylase deficiency, but the use of a DNA probe has located the gene on the long arm of chromosome 8 (White et al 1985).

3 β -Dehydrogenase deficiency

This rare form of congenital adrenal hyperplasia results in a block of steroidogenesis very early in the pathway, giving rise to severe salt-losing adrenal hyperplasia. The androgen most elevated is dehydroepiandrosterone, an androgen which causes mild virilization. The diagnosis rests on the measurement of elevated dehydroepiandrosterone. The gene encoding 3 β -dehydrogenase has not yet been cloned but it is not linked to HLA.

Androgen-secreting tumours

Androgen-secreting tumours are rare in pregnancy, but may arise in the ovary or the adrenal gland. They cause fetal virilization. When they occur in the non-pregnant woman, anovulation is induced.

Ovary

A number of androgen-secreting tumours have been reported, including luteoma (Hensleigh and Woodruff 1978, Cohen et al 1982), polycystic ovaries (Fayez et al 1974), mucinous cystadenoma (Novak et al 1970, Post et al 1978), arrhenoblastoma (Barkan et al 1984) and Krukenberg tumours (Connor et al 1968, Forest et al 1978). Not all female fetuses will be affected and there is no association with gestation and exposure. The fetus may be partly protected by the conversion of the maternally derived androgen to oestrogen in the placenta, and thus the degree of virilization is variable.

Adrenal gland

There are only two reports of adrenal adenomas causing fetal masculinization (Murset et al 1970, Fuller et al 1983). These tumours may be responsive to human chorionic gonadotrophin, and thus levels of androgen may be higher in pregnancy than in the non-pregnant state, leading to androgenization of the fetus.

Drugs

The association between the use of progestogens and masculinization of the female fetus has received much publicity, but the only progestogen proven to have such an effect is 17-ethinyl testosterone (Ishizuka et al 1962). These infants had clitoromegaly and, in some cases, labioscrotal fusion, but the risk is very small (one in 50). Gestogens which are derived from testosterone should be avoided in the pregnant woman. There have been two case reports of androgenization of female fetuses from exposure to danazol during pregnancy (Castro-Magana et al 1981, Duck and Katamaya 1981), and both babies were born with external genitalia similar to those with adrenogenital syndrome.

Associated multiple congenital abnormalities

Female intersex has been described in association with a number of multiple abnormality states, most commonly those in association with the urinary and gastrointestinal tracts. It has also been described in association with VATER (Vertebrae, Anus, Trachea, Oesophagus and Renal) syndrome (Say and Carpentier 1979).

The management of these children with masculinized genitalia is to ensure the assignment of a sex of rearing, and to modify the genitalia appropriately. In all of these rare cases, the female role has been chosen and reduction clitoroplasty performed.

46XY Disorders of Sexual Development

The normal differentiation of the gonad to become a testis has been described above, and its subsequent secretion of testosterone leads to development of the Wolffian duct and the urogenital sinus to produce the normal male internal and external genitalia. Testosterone is the predominant male sex hormone secreted by the testis, but two other processes are necessary for normal development: the conversion of testosterone to DHT by 5 α -reductase, and the presence of androgen receptors in the target cell which bind with the DHT or testosterone and produce appropriate nuclear function. Thus, a normal male genotype (i.e. XY) with a female phenotype will occur if there is:

- failure of testicular development;
- error(s) in testosterone biosynthesis; or
- androgen insensitivity at the target site.

Failure of testicular development

This group of disorders includes true gonadal dysgenesis, Leydig cell hypoplasia and the persistent Müllerian duct syndrome.

True gonadal dysgenesis

True gonadal dysgenesis is characterized by streak gonads, normal Müllerian structures and normal external female genitalia. It has been suggested that the streak gonads in these individuals were originally ovaries which contained oogonia which then subsequently underwent massive atresia, in a similar fashion to Turner's syndrome. The karyo-

type is either 46XY or 46XX, and these patients usually present in their teenage years with failure of pubertal development.

46XY partial gonadal dysgenesis

In this condition, the infants are born with ambiguous genitalia, which results from the partially dysgenetic development of the testis. The dysgenetic gonads have various histological arrangements, with poor seminiferous tubules. However, some androgen can be produced by these testes, which results in partial androgenization of the external genitalia, leading to the genital ambiguity. These children have a high risk of gonadal tumours, especially gonadoblastoma, and in these circumstances, the gonads should be removed early to prevent this development.

Leydig cell hypoplasia

Leydig cell hypoplasia is an uncommon condition of which the aetiology remains speculative. The role of fetal luteinizing hormone in normal testicular development is unknown, but it may be necessary for maturation of the interstitial cells into Leydig cells. Failure of luteinizing hormone production in the first trimester will result in Leydig cell hypoplasia and male pseudohermaphroditism (or an autosomal-recessive disorder resulting in absent luteinizing hormone receptors will cause absence of Leydig cells). This manifests as ambiguous genitalia, in both circumstances due to some androgen production by Sertoli cells. Clinically, Leydig cell hypoplasia usually presents as a phenotypical female with primary amenorrhoea and sexual infantilism, but ambiguity at birth may result in diagnosis in infancy.

46XY true hermaphroditism

These individuals have the presence of both testicular and ovarian tissue with a 46XY karyotype. It has been suggested that mutation of the SRY gene may be the aetiology of this (Berkovitz and Seeherunvong 1998).

46XX sex reversal

This nomenclature is used to describe the situation in which testicular tissue develops in someone with a 46XX karyotype. If testicular development is normal, they are referred to as '46XX males', but when testicular determination is incomplete, they are referred to as '46XX true hermaphrodites'. In 46XX males, the external genitalia are usually normal or a small percentage may have hypospadias. Clinically, they do not present until puberty, when this is delayed due to failure to be able to produce testosterone and due to the degeneration of seminiferous tubules and Leydig cell hyperplasia, which seems to occur just prior to puberty. It seems that in the majority of these individuals, the sex reversal is related to the translocation of Y chromosome sequences, including the SRY gene from the paternal Y chromosome to the paternal X chromosome (Tomomasa et al 1999). However, one-third of individuals are not found to have Y chromosome sequences in their DNA, and this means that there must be a mutation in the genomic DNA which permits testicular determination

to occur in the absence of TDF. These gene defects remain to be explained.

Errors in testosterone biosynthesis

This type of disorder accounts for only 4% of XY females, and results from deficiency of an enzyme involved in testosterone synthesis (see Figure 13.5).

20,22-Desmolase deficiency

Absence of this enzyme results in failure to convert cholesterol to pregnenolone, and a failure of subsequent steroid production. Most of the reported cases have died in early childhood due to adrenal insufficiency, but the XY individuals are all partially virilized with a small blind vaginal pouch. It is considered to be an autosomal-recessive disorder.

3 β -Hydroxysteroid dehydrogenase deficiency

This is a rare disorder which affects both adrenal and gonadal function and is again autosomally recessive. The deficiency may be complete or incomplete, and thus the degree of virilization is variable, with various degrees of hypospadias or a small blind vagina with normal internal male genitalia and absent Müllerian structures. Those individuals who have survived and reached puberty have developed gynaecomastia, presumably because the absence of testosterone during fetal life has allowed breast bud development. The diagnosis is made by elevated levels of pregnenolone and 17-hydroxypregnenolone, and low levels of corticosteroids and testosterone.

17 α -Hydroxylase deficiency

This syndrome produces a phenotype in XY individuals varying from normal female external genitalia and a blind vaginal pouch to hypospadias with a small phallus. The diagnosis is usually only made in adulthood with failure to develop secondary sexual characteristics. The impaired adrenal production of cortisol is not associated with clinical symptoms as the elevated levels of corticosterone compensate. The gonads should be removed if the patient is assigned a female gender and hormone replacement therapy instituted.

17,20-Desmolase deficiency

This enzyme defect primarily affects testosterone production and there is no adrenal insufficiency. The clinical findings

range from normal female to undervirilized male genitalia, and the endocrine findings are of very low serum levels of testosterone with normal corticosteroids. Again, diagnosis may not be made until failure of pubertal development.

17-Ketosteroid reductase deficiency

This enzyme is responsible for the reversible conversion of androstenedione to testosterone and oestrone to oestradiol. These patients almost always present at birth with female external genitalia and testes in the inguinal canal, and undergo masculinization at puberty. Those individuals to be raised as females should have their gonads removed before puberty and oestrogen therapy started at puberty.

Androgen insensitivity at the target site (Table 13.1)

In this group of patients, testicular function is normal and circulating levels of androgen are consistent with normal male development. The majority of patients present at puberty with primary amenorrhoea, but some will present with ambiguous genitalia. The defect may be 5 α -reductase deficiency or complete or partial androgen insensitivity.

5 α -Reductase deficiency

This results in failure of the conversion of testosterone to DHT in target tissues and thus a failure of masculinization of the site. In infancy, there is usually a small phallus, some degree of hypospadias, a bifid scrotum and a blind vaginal pouch. The testes are found either in the inguinal canal or in the labioscrotal folds, and Müllerian structures are absent. At puberty, elevated levels of androgen lead to masculinization, including an increase in phallic growth, although this remains smaller than normal. Seminal production has been reported (Petersen et al 1977).

It is an autosomal-recessive trait and the resulting enzyme defect gives predictable hormone profiles with normal levels of testosterone but low levels of DHT. The diagnosis is important in individuals born with ambiguous genitalia in order to assign the sex of rearing, and this should be based on the potential for normal sexual function in adult life. The gonads should be removed if the sex of rearing is to be female, and oestrogen replacement therapy is instituted at puberty.

Complete androgen insensitivity

This is an X-linked recessive disorder characterized by the clinical features of normal female external genitalia, a blind

Table 13.1 Types of androgen insensitivity and their abnormalities

Defect	External genitalia	Internal genitalia	Gonad	Phenotype at puberty
5 α -Reductase deficiency	Female or ambiguous	Male	Testis	Masculine
Complete androgen insensitivity	Female	Male	Testis	Infantile and breast growth
Partial androgen insensitivity	Ambiguous	Male	Testis	Partial masculine and breast growth

vaginal pouch, and absent Müllerian and Wolffian structures. The testes are found either in the labial folds, the inguinal canal or may be intra-abdominal.

These patients may lack the androgen receptor and may be shown to lack the gene located on the X chromosome between Xp11 and Xq13. Work by Brown et al (1982), however, suggests that there may be a variety of defects, ranging from absence of receptors to presence of a normal number of receptors which are inactive. The exact mechanism of the defects in patients with androgen receptors awaits definition.

The hormonal levels of testosterone which are elevated above normal due to increased luteinizing hormone production and the associated increase in testicular oestradiol and peripheral conversion of androgens to oestradiol promotes some breast development. Pubic hair growth depends on the degree of insensitivity but is usually rather scanty.

Patients either present with a hernial mass or with primary amenorrhoea despite secondary sexual characteristics; karyotyping makes the diagnosis. The gonads should be removed because of the malignant potential. The vagina may be of variable length and may be adequate, but those with a short vaginal pouch may need manual dilatation.

Partial androgen insensitivity

This is a complex condition which has been found to be due to a reduced binding affinity of DHT to the receptor or because the receptor binds the DHT but there are defects in the transcription to the nucleus. It is an X-linked recessive disorder and the partial expression means inevitable ambiguous genitalia with a blind vaginal pouch and phallic enlargement. The penis can be normal. The Wolffian ducts can be rudimentary or normal, but the testes are azoospermic. The most common presentation in infancy is hypospadias, with the urethra opening at the base of the phallus, and there may be cryptorchidism. At puberty, male secondary sexual characteristics develop poorly, but there is usually gynaecomastia. The management is dependent on the degree of ambiguity and subsequent choice of sex of rearing, with gonadectomy and hormone replacement therapy for those assigned a female role.

Anomalous Vaginal Development

When the vagina does not develop normally, a number of abnormalities have been described. The vagina may be partially maldeveloped, leading to a vaginal obstruction which may be complete or incomplete, or there may be total maldevelopment of the Müllerian ducts leading to various disorders.

Classification

Vaginal anomalies may be categorized as follows:

- congenital absence of the Müllerian ducts (the Mayer-Rokitansky-Kuster-Hauser syndrome);
- disorders of vertical fusion; and
- failure of lateral fusion.

Aetiology

Three mechanisms explain most vaginal anomalies. They may be familial; for example, XY females who have a hereditary disorder as described previously. Congenital absence of the vagina has been very rarely reported in XX siblings (Jones and Mermut 1974), and also in monozygotic twins with only one child affected (Lischke et al 1973).

The case of a female-limited autosomal-dominant trait was first reported by Shokeir (1978) who studied 16 Saskatchewan families in which there was a proband with vaginal agenesis. However, Carson et al (1983), in a study of 23 probands, disputed Shokeir's theory. The previous evidence with regard to monozygotic twins also makes this mode of inheritance unlikely. Polygenic or multifactorial inheritance does, however, offer some explanation that families may exhibit the trait as reported. The recurrent risk of a polygenic multifactorial trait in first-degree relatives is reported to be between 1% and 5%.

Finally, it is possible that Müllerian duct defects could be secondary to teratogens or other environmental factors, but no definite association has been demonstrated.

Epidemiology

The incidence of vaginal malformations has been variously estimated at between one in 4000 and one in 10,000 female births (Evans et al 1981). The infrequency of this anomaly makes accurate estimates of the true incidence very difficult to obtain, but when considered as a cause of primary amenorrhoea, vaginal malformation ranks second to gonadal dysgenesis.

Pathophysiology

The pathophysiology of vaginal absence may be either as a result of failure of the vaginal plate to form or failure of cavitation. Absence of the uterus and fallopian tubes indicates total failure of Müllerian duct development, but in the Rokitansky syndrome, the uterus is often present, although rudimentary, and therefore it must be failure of vaginal plate formation and subsequent vaginal development which leads to the absent vagina. Vertical fusion defects (Figure 13.6) may result from failure of fusion of the Müllerian system with the urogenital sinus, or may be due to incomplete canalization of the vagina. Disorders of lateral fusion are due to the failure of the Müllerian ducts to unite, and may create a duplicated uterovaginal septum which may be obstructive or non-obstructive, depending on the mode of development (Figure 13.7).

Presentation

Vaginal atresia

Vaginal atresia presents at puberty with complicated or uncomplicated primary amenorrhoea. In the majority who have an absent or rudimentary uterus, uncomplicated primary amenorrhoea is the presenting symptom, but those women who have a functional uterus may develop an associated haematometra and present with cyclical abdominal pain. If a haematometra does develop, there will be uterine

distension and an abdominal mass may be palpable, but more commonly, it is felt on rectal examination.

Vertical fusion defects

Here, the transverse vaginal septum prevents loss of menstrual blood and therefore cryptomenorrhoea results. Most patients present as teenagers with cyclical abdominal pain, and a haematocolpos will be palpable within the pelvis on rectal examination. The patient may also present with associated pressure symptoms of urinary frequency and/or reten-

tion. The incidence of vertical fusion defects is reported as 46% high, 35% mid and 19% low septae in the vagina (Rock et al 1982).

Disorders of lateral fusion

These patients usually present with the incidental finding of a vaginal septum which is usually asymptomatic. It may first be diagnosed during pregnancy, at which time excision will be necessary to ensure a vaginal delivery. However, these patients may present with dyspareunia caused by the septum, and in most cases, one vagina is larger than the other and intercourse may have occurred partially successfully in the larger side. In the unilateral vaginal obstruction group, presentation is usually with abdominal pain and the associated symptoms of a haematometra and haematocolpos. The confusing clinical sign is the associated menstruation from the other side, and the diagnosis may be missed if careful examination is not performed in these teenagers.

Investigation

Vaginal atresia

A patient presenting with a clinically absent vagina and no cyclical abdominal pain requires an ultrasound examination of the pelvis to determine the presence or absence of a uterus and/or a haematometra. Laparoscopy in these patients is unnecessary. Some 15% of patients with the Rokitansky syndrome suffer major defects of the urinary system, including congenital absence of a kidney; 40% of patients also have trivial urinary abnormalities (d'Alborton et al 1981). It is therefore important to perform an intravenous urogram in order to establish any abnormalities in the renal system or the presence of a pelvic kidney, which may alert the surgeon to take extra care if abdominal surgery becomes necessary.

Anomalies of the bony skeleton occur in approximately 12% of patients. These include abnormalities of the lumbar spine, the cervical vertebrae and the limbs. However, it

Figure 13.6 Disorders of vertical fusion.

Figure 13.7 Lateral fusion defects.

may be that the incidence of bony abnormalities is higher than this, as investigation of the skeletal system is rarely performed.

Transverse vaginal septum

Investigations in these patients are limited to ultrasound assessment of the uterus for the detection of a haematometra and haematocolpos, and this may also be used to assess the level of the septal defect. Again, investigation of the urinary tract is pertinent.

Lateral fusion defects

Investigations in this group are only important if there is an obstructed outflow problem, and should follow those outlined for vertical fusion defects.

Treatment

Vaginal atresia

The patient with Müllerian agenesis requires careful psychological counselling and associated therapy. The psychological impact of being informed of an absent vagina comes as an immense shock to both patient and parents. It is almost always followed by a period of depression in which many patients question their femininity and look upon themselves as abnormal females. They very much doubt their ability to enter a heterosexual relationship which will be lasting, and feel worthless both sexually and certainly as regards being a reproductive partner. In some patients, the depression can be very profound and suicide may be threatened. There is also great maternal anxiety over the aetiology, as most mothers feel that they are responsible for the abnormality. Reassurance of the mother is as important as that of the daughter in the management of the patient.

Occasionally, cultural problems arise which make management much more difficult, especially in ethnic groups where the ability to procreate is fundamental to marriage and social acceptance. These patients and their parents can be very difficult to console and often refuse to accept the situation, questioning the diagnosis of their sterility over a number of years. The immediate reaction of most patients is to request surgical correction of the abnormality to return them to 'normal'. Unfortunately, opting for surgical treatment without adequate psychological and physical preparation inevitably leads to disaster. The author recommends a minimum of 6 months of preparation before any surgical procedure is performed, and during this time, psychological support can be implemented for the patient and her parents. There are two major areas of support required: first, the correction of the loss of esteem and inevitable depression; repeated counselling sessions by trained personnel are required if these symptoms are to be overcome. The second problem involves the psychological aspect; again, prolonged counselling sessions will be required if an adequate and fulfilling sex life is going to be possible in the future. The sexual life achieved by well-managed patients can be excellent and has been reported to be comparable to that of the normal population (Raboch and Horejsi 1982, Poland and Evans 1985).

Management of the absent vagina with a non-functioning uterus

In a patient with an absent or rudimentary uterus, the creation of a vaginal passage may be non-surgical or surgical. The non-surgical technique involves the repeated use of graduated vaginal dilators over a period of 6–12 months. A vaginal dimple of at least 1 cm is necessary for this technique to succeed, and patients require support and encouragement during this time. Patients are instructed to begin with a small vaginal dilator which is pressed firmly against the vaginal dimple for a period of some 20 minutes twice a day. Pressure is exerted but pain should be avoided, and repeated use of these vaginal dilators will meet with success in approximately 90% of cases with appropriate selection (Broadbent et al 1984, Edmonds 2003). This technique was first described by Frank in 1938, and in view of its undoubted success, with no complications, this method must be attempted in all girls with an absent vagina and a 1 cm dimple before any surgical procedure is considered.

In girls with a vaginal dimple of less than 1 cm or those in whom Frank's procedure fails, vaginoplasty will be required. There are currently three techniques in popular usage: the McIndoe–Reed operation, the amnion vaginoplasty and the Williams vulvovaginoplasty.

The McIndoe–Reed procedure was first described in 1938 (McIndoe and Banister 1938) and involved the use of a split-thickness skin graft over a solid mould; this mould is placed in a surgically created space between the urethra and the rectum. This space is created digitally following a transverse incision in the vaginal dimple. Digital exploration of the space must be performed with great care as damage to the bladder or the rectum may occur. The space created must reach the peritoneum of the pouch of Douglas if an adequate length of a vagina is to be created. A split-thickness skin graft is then taken from a donor site and an appropriately sized mould is chosen. The skin graft is then fashioned over the mould with the external skin surface in apposition to the mould. The skin-covered mould is then placed in the neovaginal space, and the labia are sutured together to hold the mould *in situ*. McIndoe reported his own series of 105 patients in 1959 and had a satisfactory outcome in 80% of patients. Cali and Pratt (1968) reported on their series of 123 patients; 90% had good sexual function but 6% had major complications which were primarily fistulae, and subsequent reconstructive surgery was necessary in 8%. These complications resulted in modifications of the technique and the use of a soft material for the mould to prevent fistula formation due to pressure necrosis.

The search for an alternative material to line the neovagina and avoid the scarring of the donor skin site led to the use of amnion for the vaginoplasty procedure (Ashworth et al 1986). The technique involves the creation of a neovaginal space in the same way as described for the McIndoe–Reed procedure, but amnion obtained at the time of elective caesarean section is used to line the neovagina. The mesenchymal surface of the amnion is placed against the new vaginal surface to promote epithelialization, and the mould is kept *in situ* for 7 days and then replaced with a new amnion graft for a further 7 days. Subsequently, patients are encouraged to use dilators on a frequent basis to maintain the vaginal

passage. Again, reported success of approximately 90% has been achieved by these authors.

The Williams vulvovaginoplasty (Williams 1976) has almost no place in the management of these disorders, and is much less frequently used than in the past. In patients in whom dissection of a neovagina is impossible but the labia majora are normal, this technique is valuable. The principle of the operation is to create a vaginal pouch from the full-thickness skin flaps created from the labia majora, which are united in the midline. Following surgery and adequate healing, the patient is taught to use vaginal dilators in the same way as described in the Frank technique. There is no doubt that this does allow the patient and her partner to enjoy a sex life with mutual orgasm, but the angle of the vagina is unnatural and unsatisfactory for some patients. Although the operation is simple to perform, the psychological problems of the distorted external genitalia can be considerable.

The absent vagina with a coexistent functional uterus

This situation presents major problems, as the release of menstrual blood and the relief of associated pain are the primary aims; the creation of a normal vagina is an equally important yet secondary role. The functional uterus may be normal and a cervix may be present or absent. This situation is very rare; an operation to create a neovagina in an attempt to reanastomose a uterus which has been drained of its haematometra is highly specialized and will not be discussed further.

Complications

Some 25% of women will have some degree of dyspareunia following a vaginoplasty (Smith 1983). This is most commonly due to scarring at the upper margin of the vagina, involving the peritoneum. Similar incidences of dyspareunia occur in nearly all series and it is difficult to know how best to avoid this. It seems to occur regardless of technique, but contraction of the upper part of the vagina is difficult to avoid. The artificial vagina created in these ways acquires all the characteristics of normal vaginal epithelium, and the exposure of the grafted epithelium to a new environment means that care has to be taken to ensure it remains healthy. Four cases of intraepithelial neoplasia in neovaginas have been reported (Jackson 1959, Duckler 1972, Rotmensch et al 1983, Imrie et al 1986).

Management of disorders of vertical fusion

In these abnormalities, the type of procedure is governed by the type of abnormality. In the obstructed hymen, the procedure is extremely simple and a cruciate incision through the hymen will release the accumulated menstrual blood and resolve the problem. In obstructing transverse vaginal septae in the lower and middle thirds, surgical removal of the septum can almost always be performed transvaginally, and a reanastomosis of the upper and lower vaginal segments may be performed. Great care must be taken to ensure that the excision is adequate or a vaginal stenosis at the site of the septum will remain a problem. The high vaginal

septum is the most difficult abnormality to manage, and it is almost always necessary to perform a laparotomy in order to expose the haematometra. The passage of a probe through the uterine cavity and cervix into the short upper vagina allows a second vaginal surgeon to explore the vagina from below and excise the septum. The absent portion of vagina is usually so great that reanastomosis of the vaginal mucosa cannot be achieved, and either a soft mould is inserted and granulation allowed to occur, or an amnion-covered soft mould should be inserted to promote epithelialization. Vaginal dilatation following removal of the mould must be encouraged in order to prevent constriction of the new vaginal area.

Results

The results of surgery are extremely good when judged by sexual satisfaction. However, Rock et al (1982) reported pregnancy success following surgical correction of transverse vaginal septa, and noted that patients with a transverse vaginal septum had only a 47% pregnancy rate when the site of the septum was taken into account. If the obstruction was in the lower third, all patients achieved a pregnancy, compared with 43% in the middle third and 25% in the upper third. It is suggested that the difficulties in conceiving may be secondary to the development of endometriosis, and the higher the site of the septum, the more likely the development of this disorder may be. Thus prompt diagnosis and surgical correction are important in an attempt to preserve the maximum reproductive capacity in these patients.

Complications

Complications are primarily those of dyspareunia and failure of pregnancy, as described above.

Disorders of lateral fusion

The treatment of this condition depends on the abnormality in patients with a midline septum and no other abnormality; excision of the septum should be performed and care must be taken as these septa can be very thick and removal can be rather difficult. When resecting the septum, generous pedicles should be taken to ensure haemostasis, and the results are extremely good as the remaining tissue usually retracts and causes no problem. In patients in whom there is an incomplete vaginal obstruction, the septum needs to be removed and care must be taken to remove as much of it as possible. Failure to do this will result in healing of an ostium and repeat obstruction of the hemivagina. The results and outlook for these patients are extremely good.

Malformations of the Uterus

Classification and pathophysiology

There have been numerous classification systems for uterine malformations, varying from those based on embryological development to those based on obstetric performance. However, the most widely used classification is that of

Figure 13.8 Varieties of uterine anomalies.

Buttram and Gibbons (1979), which is based upon the degree of failure of normal development. Six categories are described:

- Class I: Müllerian agenesis or hypoplasia;
- Class II: unicornuate uterus;
- Class III: uterus didelphis;
- Class IV: uterus bicornuate;
- Class V: septate uterus; and
- Class VI: diethylstilboestrol (DES) anomalies.

Many of these uterine malformations are shown in Figure 13.8.

A separate class of uterine malformations has been identified in the presence of communication between two separate uterocervical cavities.

The pathophysiology of failure of normal union of the Müllerian ducts is not clear. As proposed in the section on vaginal agenesis, the hypothesis of teratogens has been suggested but unsupported by evidence. It is most likely that this is a polygenic or multifactorial inheritance which slightly increases the risk of a uterovaginal abnormality arising in a family with no anomalies.

Incidence

The incidence of uterine anomalies is difficult to define as it depends entirely upon the interest of the investigator and the diligence with which investigation is pursued.

Obstetric series show an incidence of uterine abnormalities ranging from one in 100 to one in 1000 (Semmens 1962). In an infertile population, the incidence increases to approximately 3% (Sanfillippo et al 1978). It is likely that the incidence of uterine malformations is greatly overestimated, as no gynaecological or reproductive problems are ever experienced in the vast majority of patients.

Presentation

Abnormal uterine development may be symptomatic or asymptomatic. The most common clinical situations that will lead to a diagnosis of malformation of the uterus are recurrent pregnancy loss, primary infertility, urological abnormalities, menstrual disorders and DES exposure.

Recurrent pregnancy loss

Recurrent pregnancy wastage in the form of abortion or premature labour is a common way in which uterine anomalies will be discovered. The role of uterine anomalies in pregnancy wastage is discussed in Chapter 21 on female infertility and Chapter 23 on recurrent miscarriage.

Primary infertility

Uterine abnormalities may be discovered during investigation of an infertile woman. However, the relationship between infertility and uterine abnormalities remains controversial.

Urological abnormalities

Not uncommonly, urologists who discover malformations of the urinary system investigate the genital system and find abnormalities. Thompson and Lynn (1966) reported that 66% of patients with a maldevelopment of the renal tract had an associated Müllerian duct abnormality. However, only 13.5% of women with anomalous renal development had anomalous uterine development. In patients with a single kidney, the most common uterine abnormality is uterus didelphis with a vaginal septum which is associated with unilateral occlusion.

Menstrual disorders

Uterine abnormalities may be responsible for a number of menstrual disorders including oligomenorrhoea, dysmenorrhoea and menorrhagia. The specific menstrual symptoms will depend on the anomaly. In an interesting study by Sorensen (1981), investigating infertile women with oligomenorrhoea, 56% of patients were found to have mild uterine abnormalities. Sorensen suggested that this oligomenorrhoea might be due to poor vascularization or steroid receptor development in the malformed uterus. With regard to dysmenorrhoea, uterine abnormalities seem to be associated with a higher incidence of primary dysmenorrhoea, although this may also be associated with obstructed outflow problems. Rudimentary hemiuteri may also be the cause of dysmenorrhoea in some women.

Diethylstilboestrol exposure

The malformations associated with DES exposure have been well described (Kaufman et al 1980). These abnormalities include a classic T-shaped uterus with a widening of the interstitial and isthmic portions of the fallopian tubes and narrowing of the lower two-thirds of the uterus, as well as non-specific uterine abnormalities with changes of cavity seen on hysterosalpingography. These patients may present with impaired reproductive function, and pregnancy wastage may be as high as 50–60%. However, as DES exposure was terminated in 1970, almost all of

these individuals will now have finished their reproductive performance.

Investigations and treatment

When uterine anomalies are suspected, a number of imaging techniques can be used to identify the abnormality. These include ultrasound, magnetic resonance imaging and hysterosalpingography. For a review, the reader is referred to Troiano and McCarthy (2004).

The value of treatment of uterine malformations is discussed in Chapter 21.

KEY POINTS

1. Gonadal differentiation into a testicle or ovary depends on the presence or absence of a Y chromosome.
2. The testis develops from the medulla whereas the ovary originates from the cortex or the primitive gonad.
3. Development of normal ovaries depends on the presence of two X chromosomes.
4. Deletion of either the short or long arms of the X chromosome may result in variable ovarian development or dysgenesis.
5. Development of the testis depends on TDF, which controls expression of the H-Y antigen, but other autosomally located genes are also involved.
6. Female intersex disorders denote external genital masculinization in patients with 46XX karyotype.
7. Differentiation of internal female sexual organs is not androgen dependent and, unlike the clitoris, the labia are only adversely affected if exposed to androgens before the 12th week of intrauterine life.
8. 21-Hydroxylase deficiency is an autosomal-recessive disorder and accounts for 90% of cases of congenital adrenal hyperplasia.
9. 21-Hydroxylase deficiency is the only adrenal enzymatic deficiency associated with the HLA gene located in chromosome 6.
10. Female fetus defeminization may follow maternal use of testosterone-related progestogens.
11. Prenatal diagnosis of congenital adrenal hyperplasia in heterozygous carriers is necessary, and treatment with dexamethasone prevents fetal inflexion.
12. Successful pregnancy following resection of the vaginal septum is inversely related to the level of the septum in the vagina.
13. Intrauterine DES exposure may lead to a T-shaped uterus with impaired reproductive function.
14. Unilateral renal aplasia is frequently associated with failure of Müllerian duct development on the same side, since both are dependent on adequate development of the mesonephric system.
15. Where there is Müllerian agenesis, the urogenital sinus forms but does not lengthen, and the vagina is short although variable in length.
16. Virilizing features at puberty require thorough investigation and sensitive management.

Introduction

Puberty and adolescence are recognized as periods involving marked endocrine changes which regulate growth and sexual development. Normal pubertal development is known to be centrally driven and dependent upon appropriate gonadotrophin and growth hormone (GH) secretion, and normal functioning of the hypothalamic–pituitary–gonadal axis. The mechanisms which control the precise timing of the onset of puberty, however, are still not clearly understood but are influenced by many factors including general health, nutrition, exercise, genetic influences and socio-economic conditions (Rees 1993). Most of the changes during puberty are gradual, although menarche is a single event that can be dated in girls. Normal puberty involves a fairly regular sequence of events between the ages of 10 and 16 years, and abnormal puberty can be defined as any disturbance in this. This chapter will provide an overview of the endocrine changes observed during normal pubertal development, and will describe the factors believed to influence the tempo of puberty and ovarian maturation before discussing some of the conditions that result in disordered pubertal development.

In broad terms, once a girl has passed menarche, she is potentially fertile and should be considered as a young woman. The degree of sexual and reproductive maturity is not always mirrored by emotional and psychological maturity, so consideration must be given to the particular needs of adolescent girls when they attend clinics and hospital with gynaecological problems.

It is recognized that adolescents have special needs. Adolescents with gynaecological problems have additional needs and often require a degree of privacy and sensitive handling. Many of the gynaecological problems encountered relate to intimate bodily functions at a time when the

individual is maturing sexually and having to deal with issues that are embarrassing and may be considered taboo. Furthermore, consideration should be given to ethnic and cultural differences, and potential problems with communication, particularly as amongst the parents from ethnic minorities, it is often the father and not the mother who can speak English. As such, the need for interpreters and information written in different languages should be borne in mind.

During puberty and adolescence, the reasons why young women attend for consultation may be broadly subdivided as follows:

- sexual health: contraception, family planning, sexually transmitted disease;
- pregnancy: wanted and unwanted teenage pregnancy;
- gynaecological complaints: menstrual cycle dysfunction, pelvic pain, ovarian cysts and gynaecological pathology, which may occur at any stage during the reproductive years; and
- disorders of sexual development: complex and rare endocrine and developmental disorders of sexual differentiation and puberty, including intersex conditions.

This chapter will deal largely with the latter group, apart from when there is overlap with other chapters (see Chapters 13, 16 and 31).

Pubertal Development

Puberty represents a period of significant growth, hormonal change and the attainment of reproductive capacity. Its onset is marked by a significant increase in the amplitude of pulsatile release of gonadotrophin-releasing hormone (GnRH) by the hypothalamus (Mauras et al 1996). This usually

occurs between the ages of 8 and 13.5 years in girls, and stimulates an increase in pituitary release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which initially occurs as high-amplitude nocturnal pulses, although eventually both daytime and nocturnal pulsatile release are established (Delemarre et al 1991). FSH and LH, in turn, act upon the ovary to promote follicular development and sex steroid synthesis. As endocrine activity is initially nocturnal, there is no point in measuring gonadotrophin or sex steroid levels during the day.

In the female, this period is characterized clinically by accelerated linear growth, the development of breasts and pubic hair, and the eventual onset of menstruation (menarche) which occurs between the ages of 11 and 16 years in most women in the UK (Stark et al 1989). Menarche is often used as a marker of pubertal development as it is an easily identifiable event which can usually be dated with some accuracy. Adrenarche, the growth of pubic hair, is due to the secretion of adrenal androgens and precedes gonadarche by about 3 years. Thus, prepubertal children often have pubic hair, although, if pronounced, this should be investigated to exclude pathological causes (see below). Whilst androgen secretion is essential, oestrogen secretion facilitates pubic hair growth.

In tandem with the onset of pulsatile GnRH secretion, there is an increase in the amplitude of GH pulses released by the pituitary. Evidence suggests that this amplification of GH secretion may be regulated by the pubertal increase in levels of both androgenic and oestrogenic hormones (Mauras et al 1996, Caufriez 1997). In addition to this action, sex steroids have been shown to stimulate skeletal growth directly and thus augment the role of GH in promoting somatic growth and development (Giustina et al 1997). During the adolescent growth spurt, there is a greater gain in sitting height (mean 13.5 cm for girls, 15.4 cm for boys) than leg length (mean 11.5 cm for girls, 12.1 cm for boys) as the spurt for sitting height lasts longer (and is longer

in boys). At this time, there is a minimum rate of fat gain and maximum attainment of muscle bulk, with differential and opposite changes in boys and girls. Ossification of the skeleton, as measured in terms of 'bone age', is helpful in determining a child's progress through puberty and as a determinant of final stature.

Rising concentrations of GH are also believed to exert some effects on circulating insulin levels, although precise mechanisms are unclear. Some authors believe that GH induces peripheral insulin resistance which leads to compensatory increases in insulin secretion (Smith et al 1988, Nobels and Dewailly 1992). Increased levels of insulin during puberty may directly stimulate protein anabolism (Amiel et al 1991). Insulin also acts as a regulator of insulin-like growth factor-1 (IGF-1) through its effects on insulin-like growth factor binding protein-1 (IGFBP-1). IGF-1 is produced by hepatic cells under the influence of GH, and has actions which stimulate cellular growth and maturation. IGFBP-1 competes with IGF receptors to bind IGF-1, thus inhibiting cellular action of IGF-1. Studies have indicated that insulin acts to suppress production of IGFBP-1 and therefore increases circulating IGF-1 bioavailability (Holly et al 1989, Nobels and Dewailly 1992). Insulin has also been shown to be a regulator of free sex steroids through the control of sex-hormone-binding globulin (SHBG) production by the liver. Studies have shown that levels of SHBG decrease during puberty and that this parallels the rising levels of insulin (Holly et al 1989, Nobels and Dewailly 1992). The endocrine interactions involved in normal pubertal development are represented in a simplified diagram in Figure 14.1.

Tempo of pubertal development

Although the endocrine changes during puberty have become better understood, the exact 'trigger' which determines the onset of pulsatile GnRH release, and thus the initiation of

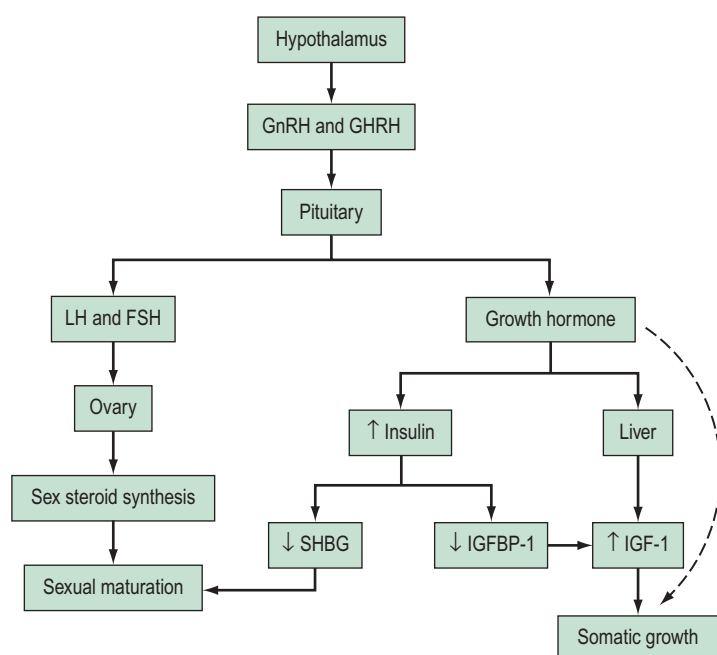

Figure 14.1 Schematic representation of the endocrine changes which regulate pubertal development. GnRH, gonadotrophin-releasing hormone; GHRH, growth-hormone-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; SHBG, sex-hormone-binding globulin; IGFBP-1, insulin-like growth factor binding protein 1; IGF-1, insulin-like growth factor-1.

Figure 14.2 Stages of breast development at puberty. Stage 1: the infantile stage, which persists from the time the effect of maternal oestrogen on the breasts disappears, shortly after birth, until the pubertal changes begin. Stage 2: the bud stage. The breasts and papillae are elevated as a small mound and there is an increase in the diameter of the areola. This stage represents the first indication of pubertal change in the breast. Stage 3: the breasts and areola are further enlarged to create an appearance similar to that of a small adult breast, with a continuous rounded contour. Stage 4: the areola and papilla enlarge further to form a secondary mound projecting above the contour of the remainder of the breast. Stage 5: the typical adult breast with a smooth rounded contour. The secondary mound present in stage 4 has disappeared.

puberty, is still unclear. The question of which factors might regulate the onset of puberty and control the rate of pubertal development has prompted extensive research. The majority of studies examining young women have used age at menarche as the key marker of sexual maturity, and have attempted to elucidate which factors are involved in the timing of this event.

The first physical sign of puberty in girls is breast development, which occurs at an average age of 10–12.5 years (Figure 14.2). Age at onset of puberty is influenced by family history, race (earlier in Afro-Caribbeans) and nutrition (earlier in obese girls, with a secular trend to younger ages). Fifty percent of girls show signs of breast development by the age of 11 years, and investigations should be performed

if there is no sign of breast development by the age of 14 years. In girls, the adolescent growth spurt occurs around 1 year after pubertal onset, while menarche occurs in the later stages of puberty at an average age of 12–15 years, at breast and pubic hair stage 4 (Figures 14.3 and 14.4; Marshall and Tanner 1969). Oestradiol concentration affects both the uterus and skeletal maturity. Most girls begin to menstruate when their bone age is between 13 and 14 years, and fewer than 20% are outside these limits. The appearance of axillary hair may antedate the rest of puberty by a few years and does not bear a constant relationship to the development of breasts as, again, it is androgens and not oestrogens that are most significant. The apocrine glands of the axilla and vulva begin to function at the time when axillary and pubic hair is appearing.

It has long been recognized that early maturing women have a tendency to be heavier for their height than their later maturing counterparts and, in contrast, that malnutrition and anorexia nervosa are associated with delayed menarche and amenorrhoea. These observed relationships between body weight and menarche led to the 'critical weight hypothesis' of Frisch and Revelle (1970), which hypothesized that attainment of a critical body weight led to metabolic changes which, in turn, triggered menarche. In further work, the investigators demonstrated that the ratio of lean body weight to fat decreased during the adolescent growth spurt in females from 5:1 to 3:1 at menarche, when the proportion of body fat was approximately 22% (Frisch 1990). They suggested that adipose tissue specifically was responsible for the development and maintenance of reproductive function, through its action as an extragonadal site for the conversion of androgens to oestrogens.

While few authors will dispute that nutrition and body weight play a role in pubertal development, the 'critical weight hypothesis' for menarche has not been supported by other studies. Cameron (1976) studied 36 British girls longitudinally, measuring weight and skinfold thickness at 3-month intervals for the 2 years before menarche to 2 years post menarche. He postulated that if a 'critical body fatness' was the true explanation for onset of menarche, he should expect to detect a reduction in the variability of his measurements at menarche compared with measurements taken before and after menarche, and this was not demonstrated in the study. In a much larger study, Garn et al (1983) analysed the triceps skinfold distributions of 2251 girls collected during three national surveys in the USA. Comparing premenarcheal and postmenarcheal girls, they confirmed that those who had attained menarche were, on average, fatter than premenarcheal girls. However, there was a marked overlap in skinfold thickness for both groups, and there was no evidence of a threshold level of fatness below which menarche did not occur. In a more recent study, de Ridder et al (1992) performed a longitudinal assessment of 68 premenarcheal school girls, including pubertal staging, skinfold measurements, waist-hip ratios and blood samples for the monitoring of gonadotrophins. They did not demonstrate a relationship between body fat mass and the age at onset of puberty or age at menarche, but did find that a greater body fat mass was related to a faster rate of pubertal development.

Although the studies above dispute the association of age at menarche with the achievement of a threshold weight or

Figure 14.3 Stages of pubic hair development at puberty. Stage 2: sparse growth of slightly pigmented hairs on either the labia or the mons pubis. Stage 3: the hair is darker and coarser, and spreads sparsely over and on either side of the midline of the mons pubis. Stage 4: the hair is adult in character but covers a smaller area than in most adults and has not spread to the medial surface of the thighs. Stage 5: hair distributed as an inverse triangle and spreading to the medial surfaces of the thighs. It does not spread to the linea alba or elsewhere above the base of the triangle.

Figure 14.4 Timing of pubic hair and breast changes and menarche. Horizontal line represents mean \pm 2 standard deviations.

body fat percentage, the association of earlier maturation in heavier girls still exists. Stark et al (1989) reported on data from 4427 girls who were part of the National Child Development Study cohort. Data relating to birth weight, age at menarche, and weights and heights measured at 7, 11 and 16 years were available. The authors reported that a larger proportion of girls with early menarche (before the age of 11 years) were heavier for their height at all ages when compared with those with late menarche (after 14 years). Interestingly, however, changes in relative weight in the years preceding menarche (ages 7–11 years) were not strongly associated with age at menarche, whereas being overweight at the age of 7 years was much more strongly associated with an early age at menarche. Birth weight was not related to age at menarche. The authors concluded that the increase in weight for height associated with early maturation actually begins well before the onset of puberty. These findings were replicated by Cooper et al (1996) who examined 1471 girls in the Medical Research Council National Survey of Health and Development. They found that girls who were heavier at 7 years of age experienced an earlier menarche; however, contrary to Stark et al, they found that birth weight was related to age at menarche and that girls with heavier birth weights experienced menarche at a later age.

Intense exercise, such as long-distance running, ballet, rowing, long-distance cycling and gymnastics, is associated with delayed menarche in young girls and with amenorrhoea in older women (Malina et al 1978, 1979, Frisch et al 1981, Baxter-Jones et al 1994). These 'endurance' sports are associated with lower body weight and percentage fat. The extent to which menarche is 'delayed' has been shown to be

related to the age at which participation in the sport begins and to the intensity of training (Frisch et al 1981). In view of the association between body weight and menarche described above, it is perhaps not surprising that girls participating in intense sporting activity experience a later age of menarche.

The influence of genetic factors on age at menarche is evident in the correlation demonstrated between mother-daughter and sister-sister pairs. Garn and Bailey (1978) analysed data from 550 mother-daughter pairs and reported a correlation of 0.25, which was adjusted to 0.23 once a correction was made for fatness. Similar correlation coefficients have been reported in other studies of mother-daughter pairs from European, African and American populations (Flug et al 1984, Benso et al 1989, Malina et al 1994, Cameron and Nagdee 1996). The strength of this 'genetic effect', however, must be interpreted carefully as the mothers' age at menarche was based on recall in most of these studies, and the accuracy of the estimation is therefore questionable. In addition, one must consider the effect of similarity in socio-economic status (and hence nutrition and fatness) that is likely to exist between mothers and daughters, and this in itself may contribute to similarity in menarcheal age.

The association between body weight and age at menarche has formed part of the basis for the explanation of the secular trend towards earlier menarche noted in the UK and other industrialized countries over the last century (Roberts et al 1971, Ostersehl and Danker Hopf 1991). It has been generally accepted that this trend has reflected improvements in nutrition, health and environmental conditions. However, a recent plateau in this trend has been observed, and even reversal in some countries, which is at present unexplained (Dann and Roberts 1993, Tryggvadottir et al 1994, Veronesi and Guerresi 1994). It has been suggested that the recent decrease in menarcheal age is related to changes in social conditioning in developed countries. Promotion of very thin women as 'ideal' role models through media and fashion has contributed to an increase in dieting in adolescent girls. Increasing participation of women in endurance sports which have intense training regimens may also be a factor related to lower body weight in young girls.

These studies all indicate that pubertal development and body weight are intrinsically linked. However, the mechanism for this relationship has not been defined conclusively. Insulin has been suggested as a modulator of the tempo of pubertal development through the regulation of IGFBP-1 and SHBG (Smith et al 1988, Holly et al 1989, Nobels and Dewailly 1992). States of overnutrition and obesity are associated with increased serum concentrations of insulin (Parra et al 1971, Rosenbaum et al 1997). Therefore, if excessive nutritional intake persists during childhood, it is possible that hyperinsulinaemia may lead to lower levels of IGFBP-1 and reduced SHBG concentrations, thus enhancing IGF-1 and sex steroid bioavailability. The converse would be true in states of malnutrition, where low levels of insulin would allow for the development of increased IGFBP-1 and SHBG levels.

However, it is still unclear whether hyperinsulinaemia in childhood is a result of obesity or if it is the cause of obesity. The roles of genetic factors, which may determine insulin production and obesity risk in childhood, are also

yet to be clearly explained. Recently, there has been much interest in the actions of the newly identified hormone leptin which is produced by adipose tissue (Sorensen et al 1996). Serum concentrations of leptin, a 167 amino acid product of white fat, have been shown to be related to body fat mass, and it is believed that leptin exerts its action on the hypothalamus to control calorie intake, decrease thermogenesis, increase levels of serum insulin and increase pulsatility of GnRH (Considine et al 1996, Sorensen et al 1996). With these actions, leptin may potentially have a role in the hormonal control of pubertal development, and some studies have shown that leptin levels do increase before the onset of puberty (Clayton et al 1997, Mantzoros et al 1997). It has been postulated that changes in circulating leptin levels may act as an initiator for the onset of puberty, and that this may explain the relationships between body fat and maturation observed by Frisch and Revelle (1970). This hypothesis is supported by the recent work of Clement et al (1998), who identified a homozygous mutation of the leptin receptor gene which results in early-onset morbid obesity and the absence of pubertal development in association with reduced GH secretion. These findings suggest that increased leptin levels associated with gains in fat mass may signal the hypothalamus to act as an important regulator of sexual maturation. It is possible that future research may clarify the role of leptin and leptin receptors in pubertal development, and may explain the variation in the timing of onset of puberty between individuals.

Ovarian and uterine development

Development of primordial follicles and secretion of oestrogens may be regarded as the final common path in the hormonal activity of puberty, and there is a close correlation between oestrogen levels and sexual maturation. The uterus grows in concordance with somatic growth, with differential increased growth of the corpus starting from approximately 7 years of age. However, the main differential increase of uterine size compared with somatic growth is only obvious after oestradiol secretion is measurably increased, and tends to occur between breast stages 3 and 4. Awareness of this comparatively late relative increase in uterine size has clinical relevance in the differentiation of arrested puberty and Müllerian agenesis, and also in the diagnosis of causes of precocious puberty. Blood oestrogen levels rise before and during puberty, and continue to do so for approximately 3 years after menarche before the normal adult follicular levels of oestrogen are seen. This gradual maturation is a reflection of the finding that many of the early cycles are anovulatory, and of the observation that the early postmenarcheal years are relatively infertile.

Ultrasound is the most suitable imaging technique for examination of the internal genitalia of girls as it is free from the risks of radiation and involves a quick, quiet and non-invasive procedure. Whilst higher resolution images can be obtained of the ovaries and uterus using transvaginal ultrasonography, only the transabdominal approach can be used in young girls and it may not always be possible to visualize both ovaries; furthermore, a full bladder is required. Nonetheless, transabdominal ultrasonography is an invaluable tool for the delineation of normal changes before and

through puberty, and also for the evaluation of paediatric disorders, such as pelvic masses and abnormal pubertal development. Ultrasonography can also be used in postmenarcheal girls to detect abnormal ovarian morphology and hence increase our understanding of common conditions such as polycystic ovary syndrome.

There are relatively few normal data on the maturation of the internal genitalia in girls, and a paper by Holm et al (1995) provides cross-sectional data of a large cohort of 166 school girls and medical students. It was demonstrated that uterine and ovarian volumes increase in size prepubertally, from as early as 6 years of age. Griffin et al (1995) demonstrated similar changes from the age of 4 years and, in their study of 153 girls, included subjects as young as 3 days. It was found that uterine shape changes constantly throughout childhood from a pear shape to a cylindrical shape and, finally, to the adult heart shape.

As girls go through puberty, the ovaries have been described as characteristically becoming multicystic due to low levels of FSH stimulating only partial folliculogenesis (Stanhope et al 1985). The multicystic appearance is also seen during resumption of ovarian activity after periods of quiescence; for example, in women who are recovering from weight-related amenorrhoea or those with hypogonadotrophic hypogonadism who are treated with pulsatile GnRH. The multicystic ovary differs from the polycystic ovary in that the cysts are larger (6–10 mm) and the stroma is of normal echogenicity. The morphological appearance of the polycystic ovary, on the other hand, requires the presence of at least 10 cysts (2–8 mm) per ovary in the presence of an echodense stroma (see Chapter 18).

Menarche

The first period occurs because there has been sufficient endometrial stimulation to result in a withdrawal bleed when there is a temporary fall in the oestrogen level. It can be associated with an ovulatory/corpus luteum sequence but this is not usual. The first menstruation simply indicates that a particular threshold has been reached in an already oscillating system, but is an obvious outward sign and of significance; menarche denotes an intact hypothalamic-pituitary-ovarian axis, functioning ovaries, the presence of a uterus and patency of the genital tract.

Menarche generally occurs within 2 years of the earliest sign of breast development and within 1 year of peak growth velocity and close to breast stage 4, usually between the ages of 10 and 16 years.

Precocious Puberty

Precocious onset of puberty is defined as occurring younger than 2 standard deviations before the average age, i.e. <8 years old in females (compared with <9 years in males). Thus, in many girls, early onset of puberty merely represents one end of the normal distribution. However, a number of pathological conditions may prematurely activate the GnRH-LH/FSH axis, resulting in the precocious onset of puberty. Furthermore, certain physical secondary sexual features (e.g. virilization without breast development) may occur in the absence of 'true puberty' (i.e.

Box 14.1 Causes of precocious puberty**Gonadotrophin dependent ('true' or 'central' precocious puberty)**

- Idiopathic (family history, overweight/obese)
- Intracranial lesions (tumours, hydrocephalus, irradiation, trauma, encephalitis)
- Gonadotrophin-secreting tumours
- Congenital brain defects, third ventricle cysts, neurofibromatosis, hamartomas
- Hypothyroidism (autoimmune)

Variants

- Premature thelarche (and thelarche variant)
- Adrenarche

Gonadotrophin independent

- Congenital adrenal hyperplasia
- Cushing's disease
- Sex-steroid-secreting tumours (adrenal or ovarian), chorion epithelioma
- McCune–Albright syndrome
- Exogenous oestrogen ingestion/administration

absent hypothalamic–pituitary activation) due to abnormal peripheral secretion of sex steroids (Box 14.1).

True precocious puberty

The appearance of pubertal physical features follows the normal sequence ('consonance'), beginning with breast development. The diagnosis is made by the finding of elevated basal gonadotrophin levels and, after stimulation with i.v. GnRH, the serum LH concentration is higher than FSH. It is important to consider intracranial pathology and arrange imaging if indicated. Pelvic ultrasound will reveal the presence of multicystic ovaries and a uterus that is developing adult proportions. Bone age will be advanced.

Premature thelarche

Premature breast development in the absence of other signs of puberty may present at any age from infancy. Breast size may fluctuate and is often asymmetrical. Bone maturation, growth rate and final height are unaffected. The cause is unknown. The diagnosis is made by the finding of elevated FSH levels (but not LH), both basal and following GnRH stimulation. Ovarian ultrasound often reveals a single large, functional ovarian cyst. Serum oestradiol concentrations are usually low and bone age is unaffected. It is important to monitor carefully in order to exclude the onset of true precocious puberty.

Autoimmune hypothyroidism may also result in isolated breast development, although this is rarely seen before 5 years of age.

Thelarche variants

There appears to be a whole spectrum of presentations between premature thelarche and true precocious puberty.

Thus, some girls with early breast development also demonstrate increased height velocity and bone maturation, and ovarian ultrasound reveals a multicystic appearance (as distinct from polycystic, see Chapter 18).

Premature adrenarche

The normal onset of adrenal androgen secretion ('adrenarche') occurs 1–2 years prior to the onset of puberty. 'Premature' or 'exaggerated' adrenarche results in mild virilization (e.g. pubic hair and acne, but not clitoromegaly). The cause is unknown. The diagnosis is made by the finding of low serum gonadotrophin levels and mildly elevated adrenal androgen levels (dehydroepiandrosterone sulphate, androstenedione). It is important to exclude late-onset congenital adrenal hyperplasia (CAH) and androgen-secreting tumours.

Congenital adrenal hyperplasia

CAH due to deficiency of the enzyme 21-hydroxylase leads to cortisol deficiency, oversecretion of adrenocorticotrophic hormone (ACTH) due to loss of feedback inhibition, and excessive production of adrenal androgens (see Chapter 11). Inheritance is autosomal recessive. Classic CAH usually presents in the neonate with ambiguous genitalia and a salt-losing crisis (see Chapter 13), whilst non-classic or late-onset CAH presents in adolescence with moderate to severe virilization (pubic hair, hirsutism, acne and clitoromegaly) and rapid growth.

The diagnosis is made by the finding of raised levels of cortisol precursors, particularly 17-OH progesterone, both at baseline and post i.v. ACTH stimulation, in both plasma and urine. Gonadotrophin levels are suppressed. Bilateral adrenal hyperplasia may be seen on abdominal ultrasound. Management of CAH is by hydrocortisone replacement therapy, which suppresses ACTH and adrenal androgen secretion (the classic presentation may also require fludrocortisone to replace aldosterone secretion).

Androgenization of the female external genitalia may lead not only to clitoromegaly but also fusion of the labioscrotal folds. There may, in addition, be a urethral fistula which may require careful repair at the time of an introitoplasty. Clitoral reduction should be undertaken with care to preserve the neurovascular bundle and sensation. Surgery may be undertaken during the neonatal period, and may be required again during adolescence. As with all surgery for intersex disorders, the precise timing is open to debate, as is the degree to which the patient, rather than her parents and doctors, is involved in the decision-making process.

Peripheral tumours**Sex-steroid-secreting tumours**

Abnormal production of androgens ± oestrogens may arise from tumours of the adrenal glands (adenomas or carcinomas), ovaries (granulosa cell or theca cell neoplasia) or teratomas. Androgen-secreting tumours are usually associated with severe virilization in young girls (<6 years old). The diagnosis is made by the finding of excessively raised circulating plasma sex hormone levels. A 24-h urine collection for steroid profile often demonstrates excess levels of sex

steroid metabolites. Gonadotrophin levels are suppressed and α -fetoprotein levels may be raised. These tumours are often palpable and an abdominal ultrasound scan will confirm the diagnosis.

Gonadotrophin-secreting tumours

Very rarely, a human chorionic gonadotrophin (hCG)-secreting hepatoblastoma, choriocarcinoma or dysgerminoma causes precocious puberty. Circulating levels of hCG are usually extremely high.

McCune–Albright syndrome

This sporadic condition results in spontaneous activation of gonadotrophin receptors and excessive sex steroid secretion independent of normal ligand binding. It is due to a somatic activating mutation of the G-protein α -subunit which also affects bones (polyostotic fibrous dysplasia), skin (café au lait spots) and potentially multiple other endocrinopathies (hyperthyroidism or hyperparathyroidism). All cells descended from the mutated embryonic cell line are affected, while cells descended from non-mutated cells develop into normal tissues. Thus, the phenotype is highly variable in physical distribution and severity. The diagnosis is made by clinical assessment, based on the presence of skin, bone and other lesions. Biopsy of affected skin may allow identification of the genetic mutation. Gonadotrophin levels are suppressed.

Management of precocious puberty

It is important to exclude severe diseases (e.g. CAH, cranial or peripheral tumours) which will require specific therapy. Following reduction in peripheral sex steroid levels, due to CAH or sex-steroid-secreting tumours, central precocious puberty may occur due to hypothalamic maturation (especially if the girl's bone age is already >11 years). Premature thelarche and thelarche variant need no treatment as there are no long-term consequences and, furthermore, treatment appears to be without effect.

Inhibition of puberty

Pituitary gonadotrophin secretion can be suppressed by constant high levels of a GnRH agonist, given by subcutaneous depot injection (e.g. leuprorelin acetate 3.5 mg monthly). Circulating sex steroid levels should become undetectable, and LH and FSH levels post i.v. LH-releasing hormone should return to prepubertal levels. The dose interval may need to be shortened to 3 weeks to fully suppress puberty. Following investigation and reassurance, however, many older girls and their parents are happy to avoid treatment. The aims of stopping puberty are:

- to avoid psychosocial problems arising from early sexual maturation; and
- to prevent reduction in final adult height due to premature bone maturation and early epiphyseal fusion. A wrist X-ray for estimation of bone age is essential in the investigation of precocious puberty, and may be used to predict final height when considering the need for treatment.

Androgen receptor blockade

Androgen receptor blocking agents, such as cyproterone acetate, finasteride or flutamide, may be used for symptomatic treatment of excess androgen production in girls with premature adrenarche.

Delayed Puberty

Delayed puberty is defined as the absence of onset of puberty by more than 2 standard deviations later than the average age, i.e. >14 years in females (compared with >16 years in males). Delayed puberty may be idiopathic/familial or due to a number of general conditions resulting in undernutrition. Absence of puberty may also be due to gonadal failure (elevated gonadotrophin levels) or impairment of gonadotrophin secretion. Occasionally, some girls enter puberty spontaneously but then fail to progress normally through puberty (Figure 14.5 and Box 14.2).

Constitutional delay of growth and puberty

Rates of skeletal and sexual maturation are closely linked, but vary widely between individuals and are influenced by family history and rate of early childhood weight gain. Although constitutional delay presents more commonly in males, this may merely reflect their higher level of concern. These girls are otherwise healthy. The diagnosis is made by exclusion, but often can only be confirmed retrospectively following spontaneous initiation of the hypothalamic–pituitary axis. It can be very difficult to distinguish hypogonadotrophic hypogonadism from constitutional delay in puberty, and therefore it is better to provide treatment and revisit the diagnosis at a later date. Appropriate investigations, after physical examination and measurement of weight

Box 14.2 Causes of delayed puberty

General

- Constitutional delay of growth and puberty
- Malabsorption (e.g. coeliac disease, inflammatory bowel disease)
- Underweight (due to severe dieting/anorexia nervosa, overexercise or competitive sports)
- Other chronic disease (asthma, cystic fibrosis, renal failure)

Gonadal failure (hypergonadotrophic hypogonadism; see Chapter 16)

- Turner's syndrome, gonadal dysgenesis and premature ovarian failure
- Post malignancy (following chemotherapy, local radiotherapy or surgical removal)
- Polyglandular autoimmune syndromes

Gonadotrophin deficiency

- Congenital hypogonadotrophic hypogonadism (\pm anosmia)
- Hypothalamic/pituitary lesions (tumours, post radiotherapy or surgery)
- Haemochromatosis/iron overload
- Rare inactivating mutations of genes encoding luteinizing hormone, follicle-stimulating hormone or their receptors

Breast stage	2 (9.2 – 13.2)	3 (10.2 – 14.2)	4 (10.8 – 15.6)	5 (11.8 – 18.6)	
Pubic hair stage	2 (9.3 – 13.7)	3 (10.0 – 14.4)	4 (10.7 – 15.1)	5 (12.2 – 16.5)	
Menarche	(11.2 – 14.8)				
Peak height velocity	(10.2 – 13.6)				
Age 10	11	12	13	14	15

and height, include assessment of serum concentrations of gonadotrophins, prolactin and thyroid function, and assessment of bone age (radial X-ray). Pelvic ultrasonography may be helpful, as is a karyotype if features of Turner's syndrome are suspected.

Turner's syndrome

Characteristic features of Turner's syndrome may not be obvious, particularly if due to chromosomal mosaicism, and karyotype should be investigated in all girls presenting with pubertal delay. Up to 25% of girls with Turner's syndrome enter puberty spontaneously; however, only 10% progress through puberty and only 1% develop ovulatory cycles. Thus, the chromosomal abnormality seems to result in premature ovarian exhaustion rather than a primary failure of ovarian development. Turner's syndrome is the most common cause of gonadal dysgenesis. In its most severe form, the XO genotype is associated with the classic Turner's features including short stature, webbing of the neck, cubitus valgus, widely spaced nipples, cardiac and renal abnormalities, and often autoimmune hypothyroidism. Spontaneous menstruation may occur (particularly when there is mosaicism), but premature ovarian failure (POF) usually ensues.

The clinical diagnosis is confirmed by the finding of a 45XO karyotype (at least 30 cells should be examined due to the possibility of mosaicism). Cytogenetic analysis should also be performed looking for the presence of Y fragments, which indicate an increased risk of gonadoblastoma, and thus the 'streak' gonads should be removed (usually laparoscopically). Serum gonadotrophin concentrations are elevated compared with adolescents of the same age, and may approach the menopausal range.

Management includes low-dose oestrogen therapy to promote breast development without further disturbing linear growth (Figure 14.6). Treatment with GH has also benefited some individuals. Cyclical oestrogen plus progestogen may be used as maintenance therapy. A regular withdrawal bleed is essential in order to prevent endometrial hyperplasia. Spontaneous conception has been reported in patients with Turner's syndrome, but is rare. However, the possibility of assisted conception and oocyte donation should be discussed at an early age.

Other causes of premature ovarian failure

POF, by definition, is the cessation of periods accompanied by raised gonadotrophin concentration prior to the age of

Figure 14.6 Breast development in Turner's syndrome following oestrogen administration. There is good areolar development but little breast tissue after several years of hormone replacement.

40 years. It may occur at any age. The exact incidence of this condition is unknown as many cases go unrecognized, but estimates vary between 1% and 5% of the female population (Coulam et al 1986). In approximately two-thirds of cases, the cause of ovarian failure cannot be identified (Conway et al 1996). It is unknown whether these cases are truly 'idiopathic' or due to as yet undiscovered genetic, immunological or environmental factors. A series of 323 women with POF attending an endocrinology clinic in London identified 23% with Turner's syndrome, 6% after chemotherapy, 4% with familial POF and 2% each who had pelvic surgery, pelvic irradiation, galactosaemia and 46XY gonadal dysgenesis (Conway et al 1996). Viral and bacterial infection may also lead to ovarian failure; thus, infections such as mumps, cytomegalovirus or human immunodeficiency virus in adult life can adversely affect long-term ovarian function, as can severe pelvic inflammatory disease.

Ovarian failure occurring before puberty is usually due to a chromosomal abnormality or a childhood malignancy that required chemotherapy or radiotherapy, from which, parenthetically, there are increasing numbers of survivors into adulthood with POF. The likelihood of developing ovarian failure after therapy for cancer is difficult to predict, but the age of the patient is a significant factor; the younger the patient, the greater the follicle pool and the better her chances of retaining ovarian function.

Adolescents who lose ovarian function soon after menarche are often found to have a Turner's mosaic (46XX/45X) or an X-chromosome trisomy (47XXX). There are many genes on the X chromosome that are essential for normal ovarian function. It would appear that two active X chromosomes are required during fetal life in order to lay down a normal follicle store. In fetuses with Turner's syndrome, normal numbers of oocytes appear on the genital ridge but accelerated atresia takes place during late fetal life. Thus, streak gonads occur and it is only the mosaic form of Turner's syndrome that permits any possibility of ovarian function. X mosaicisms are the most common chromosomal abnormality in reported series of POE, ranging from 5% to 40% (Anasti 1998). Other X chromosome anomalies may result in ovarian failure; for example, balanced translocations in the long arm of chromosome X between Xq13 and q26, which is a critical region for ovarian function.

There are a number of syndromes that are associated with POE, such as familial blepharophimosis, in which the abnormality is on chromosome 3. Galactosaemia is another rare example, in which a metabolic defect has a direct inhibitory effect on ovarian function, probably due to a build-up of galactose within the ovary that decreases the initial number of oogonia.

Polyglandular autoimmune syndromes

Antiovarian antibodies are occasionally detected in both type 1 (hypoparathyroidism, Addison's disease, mucocutaneous candidiasis) and type 2 (Addison's disease, hypothyroidism, type 1 diabetes) polyglandular autoimmune syndromes. Autoimmune ovarian failure may also occur in the absence of positive antibodies due to poor sensitivity of current assays.

Congenital hypogonadotrophic hypogonadism

Congenital hypogonadotrophic deficiency associated with complete or partial anosmia \pm other midline defects and mental retardation (Kallman or DeMorsier syndrome) may be inherited in autosomal-dominant, -recessive or X-linked recessive patterns, suggesting that a number of mutated genes may be causative. Congenital hypogonadotrophism may also occur without anosmia in isolation or in pan-hypopituitarism. The diagnosis is made by a family history or related features of Kallman syndrome. Absent LH and FSH response to i.v. GnRH stimulation may be indistinguishable from constitutional delay of puberty, and retesting may be required after completing pubertal development with exogenous oestrogen.

Management of delayed puberty

Following exclusion of other diagnoses, many patients are happy to await spontaneous pubertal development. However, severe delay in pubertal onset may be a risk factor for decreased bone mineral density and osteoporosis. In subjects with hypergonadotrophic hypogonadism, puberty may be induced from any age; however, in Turner's syndrome, delay in induction to around 14 years of age possibly permits maximal response to GH therapy (see Box 14.3).

Box 14.3 Induction of puberty for girls with ovarian failure

Ethinylestradiol

- 2 μ g daily for 6 months
- 5 μ g daily for 6 months
- 10 μ g daily for 6 months
- 15 μ g daily for 6 months
- 20 μ g daily for 6 months
- 30 μ g daily for 6 months

Menstruation may occur once a 15 μ g preparation is being used. Once bleeding occurs, a cyclical oestrogen/progestogen preparation should be prescribed, usually in the form of the contraceptive pill.

Pubertal development

Oral oestrogen therapy should be commenced at a very low dose (e.g. ethinylestradiol 2 μ g daily) and gradually increased according to breast response and age. Oral progesterone should be added if breakthrough bleeding occurs or when ethinylestradiol dose reaches 20 μ g/day. Eventually, maintenance therapy is provided either with a combined oral contraceptive pill or a conventional, cyclical postmenopausal hormone replacement preparation.

Fertility

In gonadotrophin deficiency, ovulation and fertility may be achieved by ovulation induction using either pulsatile GnRH (for hypothalamic problems) or gonadotrophin therapy (for pituitary or hypothalamic disease). If the patient with hypogonadotrophic hypogonadism is particularly anxious about future fertility, a non-therapeutic trial of exogenous pulsatile GnRH administration, via a miniature portable infusion pump, confirms pituitary responsiveness. However, induction of ovulation can be achieved, bypassing the pituitary, by direct administration of human menopausal gonadotrophin (hMG). hMG is a more suitable choice than the more recently developed recombinant FSH preparations as it also contains LH which is necessary to stimulate oestrogen biosynthesis. Patients with POE may choose assisted conception with donated oocytes.

Presentation of Congenital Anomalies of the Genital Tract (see Chapter 13)

Disorders of sexual development may result in ambiguous genitalia or anomalies of the internal genital tract, and may be due to genetic defects, abnormalities of steroidogenesis, and dysynchrony during organogenesis. Age of presentation will depend upon the degree of dysfunction caused. Ambiguous genitalia occur in approximately 1:30,000 newborns. The rate with which other congenital anomalies present varies depending upon the population studied and the age at which the problem is likely to be noticed. Population-based statistics are still lacking for many conditions, largely because patients present to different specialists (e.g. gynaecologists, paediatric endocrinologists, urologists, etc.), and there are rarely clear pathways for

communication between the different professional groups from which to create a comprehensive service for both provision of treatment and collection of data.

Patients require sensitive care by an expert multidisciplinary group that includes gynaecologists, paediatric endocrinologists, paediatric surgeons and urologists, plastic surgeons, psychologists, specialist nurses, geneticists and urologists. A network of support should be provided to the patient and her parents and family. The adolescent period is a particularly sensitive time as the individual becomes aware of her diagnosis and its impact on her sexuality, sexual function and fertility. It is particularly important to provide a seamless handover from paediatric to adult services at this time, and dedicated adolescent clinics may have an important role.

Müllerian duct abnormalities

In the absence of a Y chromosome, testis and testosterone, the Wolffian duct regresses after the sixth week of embryonic life. The Müllerian ducts then develop into the uterus and fallopian tubes, and fuse caudally with the urogenital sinus to form the vagina. Abnormalities in the process of fusion may be either medial or vertical, and result in primary amenorrhoea; complete or partial Müllerian agenesis may also occur. Renal developmental abnormalities are commonly seen in association with abnormalities of the genital tract, so assessment by intravenous urography is advisable before attempting corrective surgery.

Congenital absence of the vagina

Women with Mayer-Rokitansky-Kuster-Hauser syndrome (or Rokitansky syndrome) have a 46XX genotype and a normal female phenotype with spontaneous development of secondary sexual characteristics, as ovarian tissue is present and functions normally. The Müllerian ducts have failed to fuse and so there is vaginal agenesis. The incidence is about 1:5000 female births and may be associated with renal tract anomalies (15–40%) or anomalies of the skeletal system (10–20%). The external genitalia have a normal appearance but the vagina is short and blind ending, such that either surgery or gradual dilatation is necessary to achieve a capacity appropriate for normal sexual function. Hormone treatment is not required as ovarian oestrogen output is normal. Indeed, ovulation occurs and ovarian stimulation followed by oocyte retrieval can be performed in order to achieve a 'biological' pregnancy through the services of a surrogate mother.

The vaginal dimple can vary in length from just a slight depression between the labia to up to 5–6 cm. Vaginal dilators, made of plastic or glass, are used first to stretch the vaginal skin, and the patient is encouraged to apply pressure for 15 min twice daily with successive sizes of dilator. An adequately sized vagina is usually formed by 6 months but this may take longer, and long-term use of dilators may be required depending upon the frequency of sexual intercourse.

A number of surgical approaches have been employed to create a neovagina. The Vecchetti procedure uses the same principle of progressive dilatation, with the application of pressure from a plastic sphere in the vagina which is attached

to two wires that have been passed from the top of the vagina through to the anterior wall of the abdomen, where they are attached to a traction device that is tightened daily. Plastic surgical techniques include:

- the McIndoe vaginoplasty, in which a split skin graft is placed over a mould which has been inserted into a space created where the vagina should be;
- tissue expansion vaginoplasty, in which expansion balloons are inserted into the labia and inflated with water over a period of 2 weeks in order to stretch the labial skinfolds sufficiently to be used to fashion a vagina;
- an artificial vagina created from bowel, a technique less favoured nowadays because of problems with persistent discharge; and
- the Williams vaginoplasty, in which the labia are used to create a pouch, also rarely used nowadays because of problems with a poor anatomical result and an awkward angle for intercourse.

The diagnosis of Rokitansky syndrome can usually be made without the need for a laparoscopy. Sometimes, however, an ultrasound scan will reveal the presence of a uterine remnant (anlagon) which is usually small and hardly ever of sufficient size to function normally. If there is active endometrial tissue within the uterine anlagon, the patient may experience cyclical pain and the anlagon should be excised (usually laparoscopically).

Fusion abnormalities of the vagina

Longitudinal fusion abnormalities may lead to a complete septum that may be associated with two complete uterine horns with two cervixes, or a partial septum causing a unilateral obstruction. Excision is required to both prevent retention of uterine secretions and permit sexual intercourse. Transverse fusion abnormalities usually present with primary amenorrhoea and require careful assessment before surgery. The most common problem is an imperforate hymen in which cyclical lower abdominal pain combines with a visible haematocolpos and a bulging purple/blue hymen with menstrual secretions stretching the thin hymen. The surgery required is a simple incision which should be performed when the diagnosis is made to prevent excessive build-up of menstrual blood, which may lead to a haematometra and consequent increased risk of endometriosis (secondary to retrograde menstruation). A transverse vaginal septum due to failure of fusion or canalization between the Müllerian tubercle and sinovaginal bulb may present like an imperforate hymen, but is associated with a pink bulge at the introitus as the septum is thicker than the hymen. Greater care must be taken during surgery to prevent annular constriction rings, and the procedure should only be performed in dedicated centres by experienced surgeons. When there is a transverse septum, it has been found to be high in 46% of patients, in the middle of the vagina in 40%, and low in the remaining 14%. It is the patients in the last two groups who have higher pregnancy rates after surgery.

Müllerian/uterine anomalies

Uterine anomalies occur in 3–10% of the fertile female population and can be subdivided according to the nature of the

abnormality. They have been usefully classified by the American Society for Reproductive Medicine into six groups:

- segmental agenesis or hypoplasia, which may involve vagina, cervix, uterine corpus or fallopian tubes. Mayer–Rokitansky–Kuster–Hauser syndrome is included here;
- unicornuate uterus, with or without a rudimentary horn that may or may not contain endometrium and be connected to the main uterine cavity. On the affected side, the kidney and ureter are generally absent;
- uterus didelphis: due to partial or complete failure of lateral Müllerian duct fusion, leading to partial or complete duplication of the vagina, cervix and uterus;
- bicornuate uterus, with a single vagina and cervix and two uterine bodies, that may be completely separated or fused centrally with a partial septum;
- septate or arcuate uterus, with a septum that may be partial or complete; and
- diethylstilboestrol-related anomalies, which may demonstrate various shapes due to the effect of diethylstilboestrol.

These anomalies are often discovered by chance during coincidental investigations for infertility. The diagnosis is made by a combination of ultrasound, magnetic resonance imaging and X-ray hysterosalpingography (the latter during the course of an infertility work-up). Women with uterine anomalies are usually asymptomatic, unless there is obstruction to menstrual flow, when cyclical pain may be experienced. Whilst infertility *per se* is rarely caused by uterine anomalies, they may be associated with endometriosis if there is retrograde menstruation secondary to obstruction. Furthermore, recurrent miscarriage may be experienced by some women with uterine malformations.

Surgery is reserved for those cases where there is obstruction; for example, the removal of a rudimentary uterine horn or excision of a vaginal septum. The excision of a uterine septum has been shown to improve pregnancy outcome and should be performed by an experienced hysteroscopist. On the other hand, metroplasty (Strassman procedure) of the horns of a bicornuate uterus is seldom performed nowadays as its benefit has been questioned.

Androgen insensitivity syndrome

Girls who are phenotypically normal but have absent pubic and axillary hair in the presence of normal breast development are likely to have complete androgen insensitivity syndrome (formerly known as 'testicular feminization syndrome', a term that is no longer favoured). In this condition, the karyotype is 46XY and, whilst testes are present, there is an insensitivity to secreted androgens because of abnormalities in the androgen receptor. The incidence is approximately 1:60,000 'male' births and it is inherited as an X-linked trait (the androgen receptor is on the short arm of the X chromosome). Anti-Müllerian factors prevent the development of internal Müllerian structures, and the Wolffian structures also fail to develop because of the insensitivity to testosterone. The external genitalia appear female. In approximately 10% of cases, the defect is incomplete (partial androgen insensitivity syndrome); the external genitalia may be

ambiguous at birth, with labioscrotal fusion, and virilization may sometimes occur before puberty.

After puberty, gonadal tissue should be removed to prevent malignant transformation (dysgerminoma), which occurs in approximately 5% of cases. Exogenous oestrogen should then be prescribed; cyclical treatment is not required because the uterus is absent. The syndrome may be diagnosed in infancy if a testis is found in either the labia or an inguinal hernia, in which case both testes should be removed at this time because of the potential risk of malignancy. Some cases, however, only present at puberty with primary amenorrhoea, and removal of abdominal/inguinal testes should then be performed.

Careful psychological assessment and counselling are obligatory to allow an understanding of the gonadal dysfunction and necessity for hormone treatment. It may be helpful to describe the gonads as internal sexual organs that have been incompletely formed and which are therefore prone to develop cancer if they are not removed. In general, a completely honest approach is favoured so that the individual is provided with full information about her condition, its origins and management. It is certainly the author's experience that the vast majority of patients desire a full explanation of their condition, and respond better to treatment if they are included in the decision-making processes. Patients with these problems should be referred to centres where there are specialists experienced in their management, so that a comprehensive team approach can be provided.

There are several uncommon intersex disorders which result in primary amenorrhoea, and while their management must be individualized, it will often broadly follow the above outline. Examples are male pseudohermaphroditism, caused by 5 α -reductase deficiency, and female pseudohermaphroditism, caused by CAH (see above). In contrast to the androgen insensitivity syndrome, in these conditions, there is deficient or absent breast development, yet normal or increased pubic and axillary hair. 5 α -reductase deficiency is an autosomal-recessive condition, diagnosed by the presence of undervirilization (which may change at puberty) and an elevated testosterone: dihydrotestosterone ratio.

Cloacal anomalies

Cloacal anomalies may take a variety of forms depending upon the relative contribution of gastrointestinal, genital and renal tracts. The cloaca should be divided anteriorly into the urogenital sinus, and posteriorly into the rectum. Major surgery is often required during the neonatal period to provide anterior abdominal wall integrity and continence of faeces and urine. Several operations may be required, and the uterus and genitalia, if present, may be adversely affected such that, at puberty, there is obstruction to menstrual flow and also an increased rate of ovarian cyst formation, presumably due to ovarian entrapment restricting normal follicular growth and ovulation.

Gynaecological Complaints

Disorders of the menstrual cycle are common and often normal in adolescence, and will rarely require secondary level care unless there is underlying pathology. Most

conditions will be dealt with in an outpatient setting and will seldom require a hospital stay. The adolescent female will require careful explanation of what is normal, what can be expected and how things may change. Provision should be made to see her either alone, with her mother or, as is often the case, with a close female friend. Adolescents need to be given autonomy and ownership of their condition in order to encourage attendance for follow-up appointments.

Menorrhagia

In a young woman with intractable menorrhagia, an assessment of blood clotting may be beneficial. Disorders of haemostasis such as von Willebrand's disease, deficiencies of factors V, VII, X and XI, and idiopathic thrombocytopenic purpura are thought to increase menstrual loss. Young girls with heavy periods in the years after the menarche are very unlikely to have any pelvic pathology. A very small number of young girls have persistent heavy irregular periods associated with anovular cycles, particularly those with polycystic ovary syndrome (see Chapter 18). In these cases, sustained unopposed oestrogen levels lead to endometrial hyperplasia which may ultimately progress to carcinoma.

Primary dysmenorrhoea

In general, primary dysmenorrhoea appears 6–12 months after the menarche when ovulatory cycles have become established. The early cycles after the menarche are usually anovular and tend to be painless. The pain usually consists of lower abdominal cramps and backache, and there may be associated gastrointestinal disturbances such as diarrhoea and vomiting. Symptoms occur predominantly during the first 2 days of menstruation. Primary dysmenorrhoea does not tend to be associated with excessive menstrual bleeding. Although excessive levels of prostaglandins, leukotrienes and vasopressin have been found in primary dysmenorrhoea, the primary stimulus for their production remains unknown. The clear involvement of prostaglandins in

primary dysmenorrhoea has led to the use of prostaglandin synthetase inhibitors, such as mefenamic acid, naproxen, ibuprofen and aspirin, to treat the disorder. Ibuprofen is the preferred analgesic because of its favourable efficacy and safety profiles.

Summary

The endocrine changes during puberty are regulated by the hypothalamic–pituitary–ovarian axis which controls growth and gonadotrophin pulsatility. Insulin plays a pivotal role by its influence on IGFBP-1 and SHBG levels. Recent studies also indicate that the hormone leptin, which is secreted by fat cells and which acts on the hypothalamus to induce satiety, may influence energy metabolism and GnRH pulsatility. Body weight, nutrition, and genetic and socio-economic factors may all play a role in the initiation and timing of puberty, but the precise mechanisms still remain unclear.

Anomalous pubertal development requires careful evaluation to exclude sinister causes. Once initial investigations have been performed, it is often reasonable to hold off medical therapies and observe the rate of change. Treatments are available to suppress precocious puberty and to initiate breast development and menstruation for girls with delayed puberty or ovarian failure, respectively.

Management of all intersex conditions requires the skills of a multidisciplinary team that includes paediatric surgeons, urologists (often paediatric and adult), plastic surgeons, endocrinologists, specialist nurses, psychologists and gynaecologists, whose role is to help coordinate the transition from childhood through adolescence and then womanhood, and help with issues relating to sexual function and sexual identity, endocrinology and fertility. It is during the difficult time of adolescence that the patient usually first realizes that there are serious problems, and it is often the specialist gynaecologist who helps her to understand the diagnosis and requirements for management. The support of a skilled nurse and clinical psychologist is invaluable at this time.

KEY POINTS

1. Puberty is a coherent process involving oestrogen production, increased somatic growth and the development of secondary sexual characteristics.
2. The essential hormonal event of puberty is the augmentation of pulsatile gonadotrophin secretion, which is affected by endocrine, nutritional and psychological factors.
3. Menarche occurs after sufficient endometrium has developed to result in a withdrawal bleed when the oestrogen level temporarily falls. It usually occurs within 2 years of the earliest sign of breast development.
4. Appropriate investigation of abnormal events surrounding puberty must be based upon detailed history and examination of the patient.
5. The most common cause of delayed puberty is ovarian failure. More than half of girls with delayed puberty have chromosome anomalies.
6. Serum gonadotrophin levels are important in distinguishing hypo- and hypergonadotrophic causes of delayed puberty.
7. Oestrogen and progesterone replacement are used in primary ovarian failure to induce pubertal growth and secondary sexual characteristics.
8. Precocious puberty, where breast development occurs before the age of 8 years, is most commonly due to constitutional early development.
9. Precocious puberty requires prompt investigation and treatment in order to avoid short stature from premature closure of the epiphyses.
10. Anorexia nervosa and acute weight loss are associated with amenorrhoea.
11. The psychological stress of pubertal disorders must be recognized and dealt with sympathetically in order to avoid excessive undermining of the patient's self-confidence.
12. Oocyte donation has been successfully used to allow patients with primary ovarian failure to achieve pregnancy and have their own children.

Acknowledgements

The author wishes to thank Dr Kathy Michelmores DPhil, Department of General Practice, Royal Victoria Hospital, Newcastle and Dr Ken Ong DPhil, Department of Paediat-

rics, Addenbrookes Hospital, Cambridge for help in preparing this chapter.

Introduction

For the regulation of reproductive function, there are two major sites of action within the brain: the hypothalamus and the pituitary gland. A full understanding of the complex mechanisms involved in the fine tuning of the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) will allow the clinician to understand the effects of stress, diet, exercise and other diverse influences which can affect the pituitary–gonadal axis and result in disorders of ovulation.

The hypothalamus lies at the base of the brain between the anterior margin of the optic chiasma anteriorly and the posterior margin of the mammillary bodies posteriorly. Precise boundaries are difficult to define, but it extends from the hypothalamic sulcus above to the tuber cinereum below, which itself connects the hypothalamus with the pituitary gland via its extension distally into the pituitary stalk.

The hypothalamus is the important final pathway between the brain and the pituitary gland. Secretion of hormones from the anterior pituitary is under the control of hypothalamic-releasing or -inhibiting factors. In turn, the pituitary hormones regulate cellular growth and differentiation and functional activity in their separate target organs. Internal environmental maintenance results in multiple biochemical signals converging upon neurones within the hypothalamus, leading to release of the pituitary hormones which coordinate appropriate metabolic responses.

Anatomy of the Hypothalamic–Pituitary Axis

The portion of the hypothalamus of special interest in the control of reproductive function is the neurohypophysis, which can be divided into three regions:

- the infundibulum, which constitutes the floor of the third ventricle (often termed the ‘median eminence’) and parts of the wall of the third ventricle, which is continuous with
- the infundibular stem or pituitary stalk, which is continuous distally with
- the infundibular process or posterior pituitary gland (Figure 15.1).

The adenohypophysis consists of:

- the pars distalis or anterior lobe of the pituitary;
- the pars intermedia, the intermediate lobe; and
- the pars tuberalis, which is a thin layer of adenohypophyseal cells lying on the surface of the infundibular stem and infundibulum.

The anterior pituitary does not normally receive an arterial vasculature but receives blood through portal vessels. The arteries supplying the median eminence and infundibular stalk empty into a dense network of capillaries, which are heavily innervated and drain into the portal venous plexus. In the human, these are present on all sides of the infundibular stalk, particularly posteriorly. These lead to the anterior pituitary formed by vessels from the median eminence and upper stalk joined ventrally by the short portal vessels arising

Figure 15.1 Anatomy of the hypothalamus and pituitary.

in the lower infundibular stalk. Some 80–90% of the blood supply to the anterior pituitary is provided by the long portal vessels; the remainder comes from the short portal veins. The sinusoids of the adenohypophysis thus receive blood that has first traversed capillaries residing in the neurohypophyseal complex, and this unique relationship provides the basis for the view that the hypothalamus regulates the secretion of adenohypophyseal hormones through neurohormonal mechanisms involving hypothalamic-releasing and -inhibiting factors.

In contrast, the neurohypophysis — posterior pituitary — is an extension of the hypothalamus and the neurosecretory neurones of the supraoptic and paraventricular nuclei. These neurones release vasopressin, oxytocin and their associated neurophysins.

Neural connections

There are numerous and extensive neural pathways connecting the hypothalamus with the rest of the brain. The majority of afferent hypothalamic nerve fibres run in the lateral hypothalamic areas, whilst efferent pathways are more medially placed. One important efferent connection is the supraopticohypophyseal nerve tract carrying fibres from the supraoptic and paraventricular nuclei to the infundibular process of the pituitary, whilst other fibres carry hypothalamic-releasing or -inhibiting factors from the medial and basal parts of the hypothalamus to the anterior pituitary (Figure 15.2).

Gonadotrophin-releasing hormone (GnRH)-secreting neurones appear in the medial olfactory placode and enter the brain with the nervus terminalis, a cranial nerve that projects from the nose to the septal preoptic nuclei in the

Figure 15.2 Representation of neurochemical interactions which are important in the control of gonadotrophin-releasing hormone (GnRH) secretion.

brain. By migration during embryogenesis, the cells, between 1000 and 3000 GnRH-producing neurones, predominantly settle in the arcuate nucleus of the hypothalamus (Schwanzel-Fukunda et al 1989). Failure of this migration has been shown to result in Kallmann's syndrome; a disorder associated with an absence of GnRH secretion and a defect of smell-anosmia (a failure of both olfactory axonal and GnRH neuronal migration from the olfactory placode). A 5–7-fold increased frequency of this condition is found in males, indicating that an X-linked transmission is the most common, although autosomal-dominant and autosomal-recessive modes of transmission have also been established (Waldstreicher et al 1996).

The mutations responsible for this syndrome result in the failure to produce a protein, homologous to members of the fibronectin family, responsible for cell adhesion and protease inhibition that is necessary for migration of these neurones (Bick et al 1992). GnRH neurones have cilia — as do olfactory epithelial cells in the nose — and the olfactory origin and structural similarity of these cells suggest an evolution from reproduction controlled by pheromones.

Hypothalamic Regulation of Pituitary Secretion

Considerable efforts have been made in the past 25 years to identify, characterize and synthesize the substances thought to be produced in the neural elements of the infundibulum. Several substances which can either stimulate or suppress the rate of release of one or more hormones from the pituitary gland have been found in the infundibular complex. These can be classified into hypophysiotrophic, neurohypophyseal and pituitary peptide hormones and are listed in Table 15.1. Other substances will probably be added to this list in the future.

Disorders of hypothalamic control of metabolic as well as reproductive hormones can influence the hypothalamic–pituitary–ovarian axis. For example, reproductive dysfunction may be associated with thyroid deficiency or excess,

Table 15.1 Hypothalamic and pituitary hormones

Hypothalamic hormones	
Gonadotrophin-releasing hormone	GnRH
Thyrotrophin-releasing hormone	TRH
Corticotrophin-releasing factor	CRF
Growth-hormone-releasing hormone	GHRH
Somatostatin	
Prolactin-inhibiting factor	PIF
Growth hormone secretagogue receptor	Ghrelin

Growth hormone	GH
Thyroid-stimulating hormone	TSH

**Figure 15.3** The structure of pre-pro-gonadotrophin-releasing hormone (GnRH). Highlighted is the decapeptide of the active molecule GnRH (molecular weight 1181). Sites of cleavage from the gonadotrophin-associated peptide are shown, as well as the main sites of enzymatic degradation of GnRH by endo- and carboxyamidase peptidases in the pituitary.

adrenocorticotrophic hormone (ACTH) excess (Cushing's syndrome) or growth hormone excess (acromegaly).

Further discussion in this chapter will be restricted to the roles played by GnRH, prolactin, dopamine and other neurotransmitters controlling the rates of release and synthesis of the gonadotrophins.

GnRH

In 1971, Schally et al isolated pure preparations of porcine LH-releasing hormone (LHRH) from hypothalamic extracts. Subsequently, its structure was discovered and synthesis was achieved (Matsuo et al 1971a,b). The finding of FSH-releasing activity of this LHRH led to the hypothesis of a single hypothalamic-releasing hormone, GnRH, controlling secretion of both LH and FSH from the pituitary gland, with the suggestion that sex steroids might play a role in modulating the proportions of LH and FSH released. The amino acid sequence of GnRH is shown in Figure 15.3; it is a decapeptide secreted with a large pre- and postprecursor molecule.

GnRH neurone system

The GnRH neurone system has been mapped in detail using primarily immunocytochemical methods. The GnRH neurones are not grouped into specific nuclei but form a loose network in several anatomical divisions. However, GnRH neurone bodies are found principally in two areas: the pre-optic anterior hypothalamic area and the tuberal hypothala-

mus, particularly the arcuate nucleus and periventricular nucleus. Axons from GnRH neurones project to many sites in the brain; the most distinct tract is from the medial basal hypothalamus to the median eminence, where extensive plexuses of boutons are found on the primary portal vessels. GnRH, then, has ready and direct access to the anterior pituitary gonadotroph cells via the portal capillary plexus (see Figure 15.2). There are also numerous projections of GnRH-secreting neurones to the limbic system and the circumventricular organ, other than the median eminence. The role of these connections is currently unknown, but they may connect with other cells or GnRH may bind to different receptors (type II) which may modulate sexual behaviour or sexual arousal.

The GnRH terminals in the median eminence remain outside the blood-brain barrier and can therefore be exposed to chemical agents within the general circulation. The GnRH neurones themselves have receptors for a number of neurotransmitters, in common with other neurones, and release them in their contacts with other neurones. In addition, their activity and release of GnRH can be influenced by GnRH agonists and antagonists. Exposure to GnRH agonists causes a greater release of GnRH but at less frequent pulse intervals. Exposure to GnRH antagonists induces a slower and non-pulsatile release of GnRH. Hence, GnRH neurones have an internal feedback loop for control of GnRH release through receptors for their own secretory product.

It has been estimated that there may be as few as 2000–3000 GnRH neurones dispersed within the hypothalamus,

located predominantly in the preoptic and mediobasal areas. Considerable reduction in number can occur without affecting the pulsatile release of gonadotrophins. The pulsatile nature of gonadotrophin release is dependent upon small numbers of GnRH neurones working in synergy; the so-called 'pulse generators'.

Regulation of gonadotrophin secretion by GnRH

The GnRH gene sequence was first isolated by Seeburg and Adelman in 1984. The GnRH decapeptide is derived from the post-translational processing of a larger precursor molecule that has been termed 'pre-pro-GnRH'. This appears to be a tripartite structure with a preceding 23-amino acid sequence joined to the decapeptide GnRH, which is then attached via a 3-amino acid sequence, glycine-lysine-arginine (GLY-LYS-ARG), to a 56-amino acid terminal peptide, which is termed the 'gonadotrophin-associated peptide' (GAP). The post-GnRH-decapeptide GLY-LYS-ARG 3-amino acid section is an important site for proteolytic processing. GAP itself is thought to have some prolactin-inhibiting properties (Figure 15.3). GnRH genes are encoded from a single gene located on the shorter arm of chromosome 8.

Using radioimmunoassays, GnRH has been demonstrated in the hypophyseal portal blood from a number of animal species (Carmel et al 1976). Electrical stimulation of the preoptic area of the brain in female rats on the day of pro-oestrus increases the GnRH concentration in portal blood, and the stimulus induces a marked release of LH from the anterior pituitary. In contrast, administration of antibodies against GnRH prevents this electrically stimulated LH release. These data provide evidence favouring a cause-and-effect relationship between GnRH release by the hypothalamus and LH release by the anterior pituitary.

It is now firmly established that GnRH can stimulate the secretion of both LH and FSH in animals and humans. Following intravenous administration of synthetic GnRH, a significant rise in serum LH, and sometimes FSH, will be seen within 5 min, reaching a peak within approximately 30 min, but FSH peaks are often delayed further. LH release has a linear log-dose relationship up to doses of 250 µg but no such relationship can be found for FSH.

In the female, the magnitude of gonadotrophin release, particularly LH, in individuals varies with the stage of the menstrual cycle, being greatest in the preovulatory phase, less marked in the luteal phase and least in the follicular phase of any individual cycle (Yen et al 1972, Shaw et al 1974) (Figure 15.4).

GnRH is thus the humoral link between the neural and endocrine components controlling LH and FSH release.

Mechanism of action of GnRH on pituitary cells

The first step in the action of GnRH on the pituitary gonadotroph is recognition of a specific receptor. GnRH receptor complexes often form clusters and become internalized, then undergo degradation in the lysosomes. The receptor fragments then pass back rapidly to the surface of the cell. This recycling process is causally related to upregulation of the receptor by GnRH. GnRH receptors tend to be of 60 kDa,

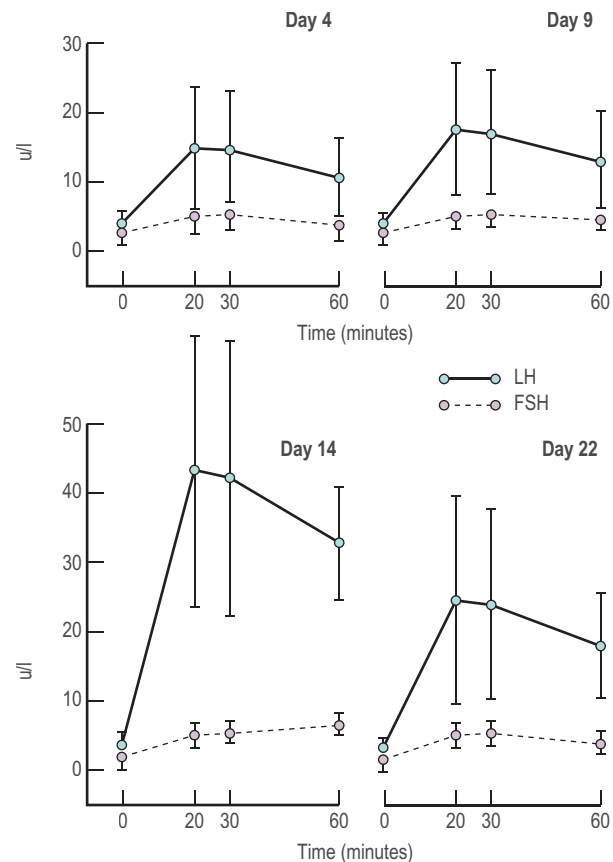

Figure 15.4 Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release following 100 mg gonadotrophin-releasing hormone at different phases of the same menstrual cycle in six normal women (mean ± SD).

From Shaw RW, Butt WR, London DR, Marshall JC 1974 Variation in response to synthetic luteinizing hormone-releasing hormone (LHRH) at different phases of the same menstrual cycle in normal women. *Journal of Obstetrics and Gynaecology of the British Commonwealth* 81:632–639.

to be glycoproteins and to have a transmembrane character of a complex nature with seven transmembrane domains. A negatively charged domain interacts predominantly with ARG in position 8 of the GnRH molecule.

The transmembrane domains have many formats which are common to humans and other species, and ligand-binding sites are fairly superficial within the receptor. In the human, the C-terminal tail is lost on the type 1 receptor (as found in the pituitary). Thus, once GnRH binds to the receptor, decoupling does not occur rapidly. This may be beneficial in allowing protracted LH release to occur.

Various GnRH agonists and antagonists have different binding ligands. An understanding of the site and mechanisms of binding to the GnRH receptor have allowed specific structural changes to be made to GnRH analogues to produce more potent pharmacological agents and to attempt to develop non-peptide antagonists.

Prolonged exposure to GnRH leads to suppression of LH release, called 'downregulation', which is associated with reduced numbers of GnRH receptors. This phenomenon is vitally important in understanding the mechanism of action of the GnRH analogues.

There are three principal positive actions of GnRH on gonadotrophin secretion:

- synthesis and storage (to reserve pool) of gonadotrophins;
- activation — movement of FSH and LH from the reserve pool to a pool for direct secretion — self-priming action; and
- immediate release (secretion) of gonadotrophins.

The binding of GnRH to its receptor induces a complex series of intracellular responses, which result in hormone secretion and biosynthesis of the α and β subunits of LH and FSH. In addition, dimerization of α and β subunits and the glycosylation processes are induced. The mechanism of action of GnRH is depicted in Figure 15.5. Within seconds of GnRH binding to and activating GnRH receptors on the pituitary gonadotrophs, intracellular free Ca^{2+} concentrations increase. This Ca^{2+} is initially mobilized from intracellular stores (e.g. endoplasmic reticulum) but also, to maintain sustained LH release, extracellular Ca^{2+} enters the gonadotroph through receptor-regulated voltage-dependent Ca^{2+} channels.

The initial mobilization of intracellular Ca^{2+} is induced by inositol triphosphate, released as a consequence of receptor activation of the membrane-bound phospholipase-C enzyme. Diacylglycerol is also released by the action of phospholipase-C and in turn activates the phosphorylating enzyme protein kinase C. The adenylyl cyclase complex is also stimulated and cyclic adenosine monophosphate (cAMP) is generated. Ca^{2+} , protein kinase C and cAMP then interact to stimulate release of stored LH and FSH and subsequent biosynthesis (for review, see Clayton 1989).

Figure 15.5 Schematic representation of gonadotrophin-releasing hormone (GnRH)-receptor signal activation. GTP, guanosine triphosphate; PLC, phospholipase-C enzyme, AMP, adenosine monophosphate; cAMP, cyclic AMP; P, phosphate group.

GnRH agonist analogues

The current generation of GnRH analogues in clinical use are predominantly agonists. GnRH is degraded by peptidases in the pituitary and hypothalamus which cleave the native decapeptide at the Gly⁶-Leu⁷ bond and at position 10. Substitution at position 6 with another amino acid renders the analogue less susceptible to enzymatic breakdown, resulting in a half-life 2.5–6 times longer than the native GnRH, whilst still allowing the analogue to bind to the pituitary gonadotroph GnRH receptor site. Several agonistic analogues are available for clinical use (see Table 15.2). Following an initial few days of increased secretion of LH and FSH after the first administration of a GnRH agonist, downregulation of the GnRH receptor is achieved with subsequently suppressed release of LH and FSH, and hence a reduced stimulus to the ovary resulting in failure of follicle growth and reduced ovarian steroidogenesis.

GnRH antagonist analogues

GnRH antagonists are characterized by multiple modification of the amino acid sequence of native GnRH; predominantly the pyroglutamic and glycine termini (position 1 and 10) and deletion and substitution of hydrophobic D amino acids at positions 2 and 3 (see Table 15.2).

GnRH antagonists bind to the GnRH receptor without affecting its internalization and initiating gonadotrophin synthesis and release. The GnRH antagonists have the advantage over agonists of immediately reducing circulating gonadotrophin levels with rapid reversal on withdrawal. However, to date, the compounds available are of relatively low bioactivity and hydrophobic, requiring repeated daily administration. Their clinical roles are mainly restricted to their use to prevent premature luteinization in assisted conception cycles.

The wide-ranging group of clinical conditions in which GnRH, GnRH agonists or GnRH antagonists have found application are listed in Box 15.1. These are discussed in greater depth in Chapters 22 and 32–34.

Modulatory Role of Monoamines, Other Neurotransmitters and Second Messengers on GnRH Secretion

Past studies indicated that LH release and ovulation were dependent upon drug-affected neural stimuli of both cholinergic and adrenergic origin. The infundibulum contains large stores of noradrenaline (norepinephrine), a lesser quantity of dopamine and a small amount of adrenaline (epinephrine) (Figure 15.6).

Dopamine and noradrenaline are synthesized in nerve terminals by decarboxylation of dihydroxyphenylalanine (DOPA), itself derived from hydroxylation of tyrosine.

Dopamine

The hypothalamic tuberoinfundibular dopaminergic pathway is formed by neurones, with cell bodies located in the arcuate nucleus and axons which project to the external layer of the median eminence in close juxtaposition to portal

vessels. The coexistence of dopamine- and GnRH-containing axons in the same region of the median eminence suggests the possibility of dopaminergic involvement in the control of gonadotrophin secretion.

The addition of dopamine to pituitaries incubated with hypothalamic fragments increases the release of LH, while the addition of phentolamine, an α -receptor blocker, prevents dopamine-induced LH release. These early in-vitro experiments suggested that the hormonal background was capable of modifying the response to dopamine, since it seemed ineffective in ovariectomized animals or during oestrus or dioestrus day 1 of the oestrous cycle. Dopamine was more effective at pro-oestrus or in oestrogen- and

**Figure 15.6** Chemical structure of biogenic amines.

progesterone-primed rats (McCann et al 1974, Ojeda and McCann 1978).

In humans, the inhibitory role of dopamine and its agonists on LH, as well as that of prolactin release, has been demonstrated (LeBlanc et al 1976, Lachelin et al 1977). Elevated levels of prolactin can also stimulate dopamine turnover in the hypothalamus, and it is postulated that the stimulated dopamine secretion alters GnRH secretion and hence reduces FSH and LH release in situations of hyperprolactinaemia. Hence, dopamine in the human may principally have an inhibitory effect on GnRH secretion.

The contradictory roles played by dopamine in GnRH release are, in all likelihood, the consequence of more than one action of dopamine on the GnRH-secreting neurone. The steroid environment appears to modify the components involved in the dopaminergic control of GnRH secretion, with oestrogen appearing to affect the population of excitatory or inhibitory dopamine receptors, and suggesting that the feedback control of GnRH output by oestrogen is partly exerted at a hypothalamic level by reducing dopamine neuronal activity.

Noradrenaline

Most experimental evidence supports a stimulatory role for noradrenaline in the control of gonadotrophin release.

Turnover of hypothalamic noradrenaline is increased during the preovulatory surge of gonadotrophins at pro-oestrus, and noradrenaline synthesis in the anterior hypothalamus is enhanced in ovariectomized rats. These effects on GnRH secretion appear to be mediated by α receptors, since phenoxybenzamine, an α blocker, suppresses the postcastration rise in gonadotrophins in male rats, and phentolamine blocks the pulsatile release of LH in ovariectomized monkeys (for review, see McCann and Ojeda 1976).

Selective blockade of noradrenaline synthesis prevents the preovulatory LH surge and that induced by gonadal steroids; the above data suggest that noradrenergic terminals in the preoptic or anterior hypothalamic area synapse with GnRH neurones involved in the control of the preovulatory surge of gonadotrophins.

Most of the cell bodies that synthesize noradrenaline are located in the mesencephalon and lower brainstem, and these cells also synthesize serotonin. The axons from these cells ascend into the medial forebrain bundle to terminate in various brain structures including the hypothalamus. The probable mode of action of catecholamines is to influence the frequency of GnRH release (see Figure 15.7).

Serotonin

High concentrations of serotonin are found in the median eminence, with most of the serotonin-containing neurones originating from the raphe nucleus in the midbrain-pons area. Present evidence shows that serotonin plays a

predominantly inhibitory role in gonadotrophin release (see McCann and Ojeda 1976).

Neuropeptide Y

Gonadal steroids regulate the secretion and gene expression of neuropeptide Y in hypothalamic neurones (Sahu et al 1992). Neuropeptide Y stimulates pulsatile release of GnRH and potentiates gonadotrophin response to GnRH (Pau et al 1995). In the absence of oestrogens, neuropeptide Y inhibits gonadotrophin secretion, and increased amounts of neuropeptide Y are found in cases of under-nutrition and the cerebrospinal fluid of women with anorexia and bulimia nervosa. These findings explain a link between under-nutrition and suppressed LH and FSH secretion in those conditions.

Endogenous opioids

Endogenous opioids play a central role in the neural control of gonadotrophin secretion by way of an inhibitory effect on hypothalamic GnRH secretion. These are a fascinating group of peptides, with 'endorphins' being the name coined to denote a substance with morphine-like action, of endogenous origin, in the brain. Endorphin production is regulated by gene transcription, and since these are precursor peptides, all opioids are derived from three precursor peptides:

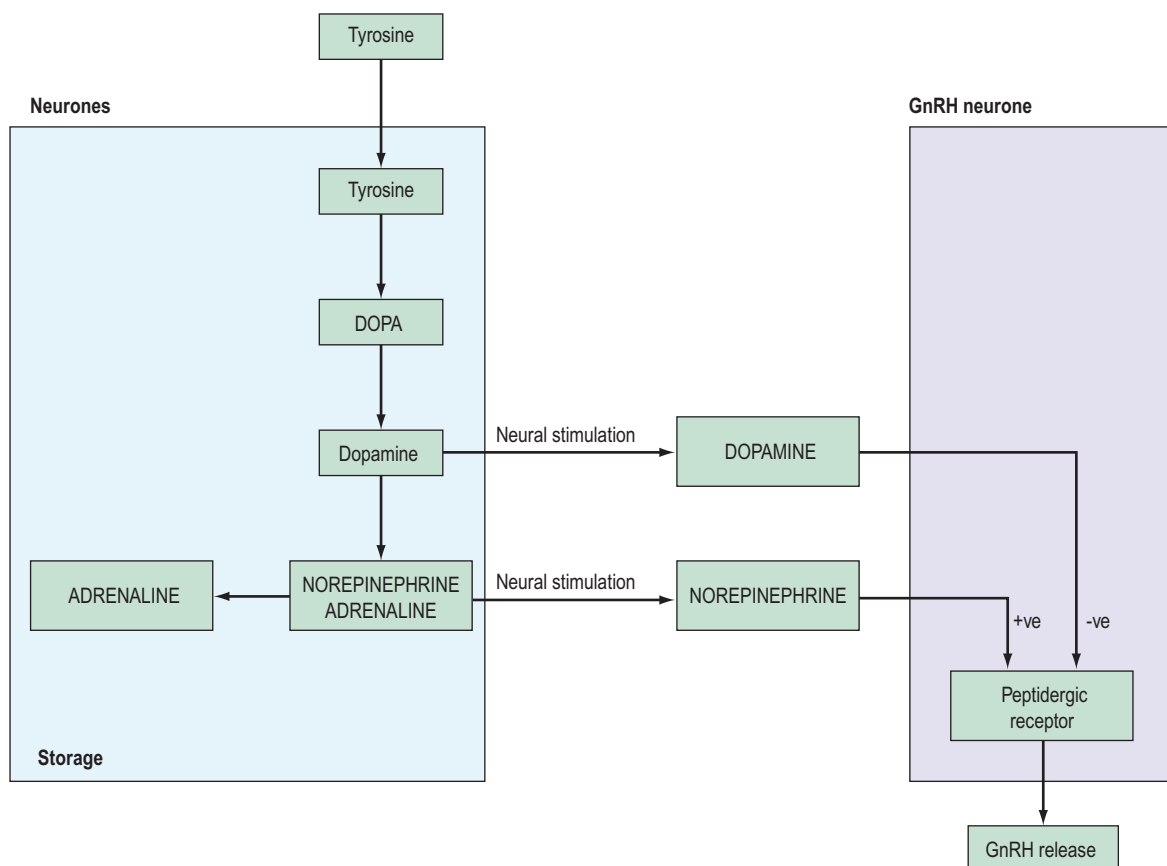

Figure 15.7 Opposing roles of dopamine and noradrenaline on the release of gonadotrophin-releasing hormone (GnRH).

- pro-opiomelanocortin is the source of endorphins;
- pro-enkephalin A and B are the source of enkephalins; and
- pro-dynorphin yields dynorphins.

A single injection of morphine, administered to oophorectomized monkeys, brings about immediate cessation of GnRH pulse generation (Yen et al 1985). Hypothalamic opioidergic neurones are found in the arcuate nucleus of the medial basal hypothalamus, in close contact with GnRH neurones. The administration of an opioid antagonist, naloxone, produces an increased frequency and amplitude of GnRH and LH secretion. These changes are most marked in the luteal phase of the cycle, and it is thought that the negative feedback of oestrogen may partly be effected through opioid-induced inhibition of GnRH secretion (Ropert et al 1981), as is the negative feedback of progesterone on GnRH secretion.

Changes in opioid tone seem to mediate the hypogonadotrophic state seen in hyperprolactinaemia, exercise and other causes of hypothalamic amenorrhoea. Treatment of patients with hypothalamic amenorrhoea (who have suppressed GnRH pulsatile secretion) with naltrexone — an opioid receptor blocker — allows return of pulsatile LH and FSH secretion and return of ovulation (Wildt et al 1993).

Corticotrophin-releasing hormone

Experimental studies indicate that corticotrophin-releasing hormone inhibits hypothalamic GnRH secretion both directly and by augmenting endogenous opioid secretion. Corticotrophin-releasing hormone infusions inhibit gonadotrophin release in primates (Xiao et al 1989), and suppress the electrophysiological activity of the GnRH pulse generator (Knobil 1989). Women with hypothalamic amenorrhoea have increased levels of cortisol in their circulation, suggesting that this is the mechanism by which stress influences the hypothalamic–pituitary–ovarian axis.

Leptin

Leptin, identified in 1994, is a 167-amino acid protein transcribed by the *ob* gene. The human leptin gene is on chromosome 7q31, and leptin is mainly produced in white adipose tissue with a small amount from brown adipose tissue. In humans, leptin concentrations increase with the onset of puberty, and low levels may contribute to the amenorrhoea seen in anorexia nervosa. Leptin only acts in the hypothalamus where it can produce rapid synaptic modulatory effects and increase GnRH release from the medial basal hypothalamus. Nocturnal changes in LH pulse parameters are associated temporarily with the rise in plasma leptin at night. These fluctuations in leptin are synchronized with serum LH changes. Leptin's predominant role is to act as an adipostat, having the capacity to improve glucose homeostasis and to stimulate energy utilization by increasing thermogenic activity and capacity.

Prolactin

Prolactin gene expression occurs on the lactotrophes of the anterior pituitary gland, in the myometrium and decidualized endometrium. Differences in mRNA in these sites indi-

cate that there are differences in prolactin gene regulation, and only that secreted by the pituitary gland is likely to be relevant in feedback on the hypothalamic–pituitary–ovarian axis. Transcription of the prolactin gene is regulated by a transcription factor which binds to the 5' promoter region, and this is also involved in growth hormone and TSH secretion. The main function of prolactin is in lactogenesis, and the secretion of prolactin is under the inhibitory control of hypothalamic dopamine released into the portal circulation. In addition to direct inhibition of prolactin gene expression, dopamine binding to the D₂ receptor inhibits lactotrophe development and growth.

Several factors exert a stimulatory effect on prolactin secretion, particularly thyrotrophin-releasing hormone, vasoactive intestinal peptide and oestrogen, whilst endogenous opioids inhibit release, probably by modulating the dopaminergic neurones.

Elevated circulating levels of prolactin result in reduced pulse amplitude and frequency of gonadotrophin release with resultant anovulation during lactation and in conditions which cause hyperprolactinaemia.

Other Neurotransmitters and Second Messengers

Other neurotransmitters may play a less important role in the regulation of GnRH neurones. Acetylcholine and γ -aminobutyric acid stimulate LH release. Both these agents are far more common as neurotransmitting agents than dopamine or noradrenaline in central nervous system nerve terminals in general, but their importance in GnRH neuronal activity seems to be less than that of dopamine and noradrenaline.

The intrapituitary paracrine–autocrine system

Growth factors and cytokines provide a paracrine–autocrine system which regulates cell development and replication, and pituitary hormone synthesis and secretion. As with other organs in the body, the pituitary contains epidermal growth factors, fibroblast growth factors, insulin-like growth factors, interleukins, activin, inhibin, endothelin and many others. Interactions between all of these substances constitute a complex interplay, but one group of compounds are better understood — those of the activin-inhibin and follistatin substances (see Figure 15.8).

Inhibin

Inhibin is secreted by granulosa cells in the ovary and selectively inhibits FSH but not LH secretion. Inhibin consists of two peptides — the α and β subunits — linked by a disulphide bond. Two forms of inhibin have been purified — inhibin A and inhibin B with identical α subunits but separate, although similar, β subunits. Messenger RNA for the α and β subunits is found in granulosa cells but also in pituitary gonadotrophes. Whilst inhibin predominantly suppresses FSH secretion, limiting the numbers of follicles recruited at the start of a cycle, cells actively synthesizing LH respond to inhibin by increasing GnRH receptor numbers. Inhibin A reaches peak levels in the luteal phase

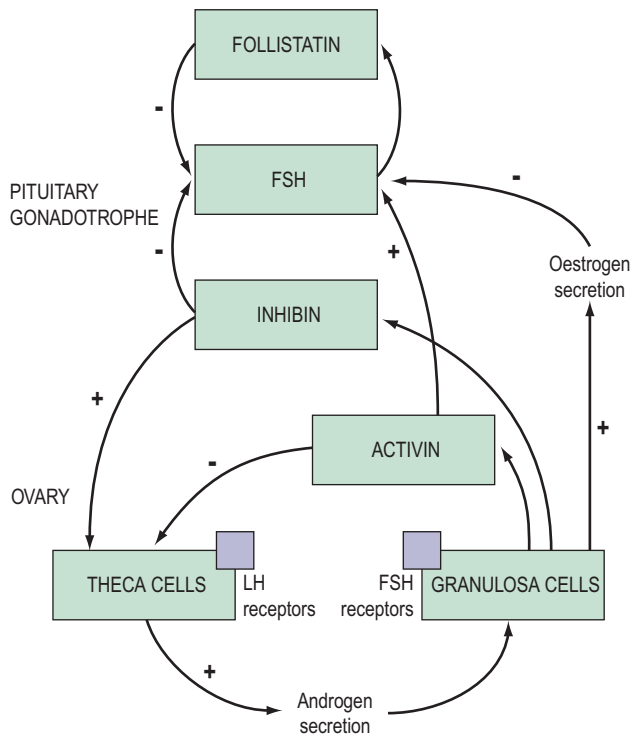

Figure 15.8 Paracrine and autocrine control of follicle-stimulating hormone (FSH) and release and function. LH, luteinizing hormone.

and falls in concentration as the corpus luteum undergoes luteolysis.

Activin

Activin is produced by granulosa cells but is also present in pituitary gonadotropes. It contains two subunits identical to the β subunits of inhibin A and B, but some variants of the β subunits have also been identified, although their role and function are not thought to be important. Activin augments the secretion of FSH and inhibits prolactin, ACTH and growth hormone response (Corrigan et al 1991, Blumenfeld 2001). Activin increases pituitary responsiveness to GnRH by enhancing GnRH receptor formation, and its effects are blocked by inhibin and follistatin.

Follistatin

This is a peptide secreted by a variety of pituitary cells including gonadotrophes. It inhibits FSH synthesis and secretion, and the FSH response to GnRH by binding to activin and thus decreasing the activity of activin (Besecke et al 1997).

Overview of GnRH secretion

GnRH thus stimulates gonadotrophin synthesis and secretion as well as activin-enhancing and follistatin-suppressing GnRH activity. Numerous other neurotransmitters and ovarian steroids also interplay in altering and modifying pituitary responsiveness to GnRH, which results in the various changes on pulse amplitude and frequency observed throughout the menstrual cycle.

Source: Shaw 1975, unpublished data.

Modulatory Effect of Ovarian Steroids

Negative feedback

Negative feedback control or inhibition of pituitary LH and FSH release has been postulated since 1932, when Moore and Price considered that the ovary and adenohypophysis were linked in a rigid system of hormonal interactions. The quantitative relationship between ovarian steroids and gonadotrophin release can be demonstrated by disturbing the negative feedback loop by oophorectomy which produces, over a period of days, an increase in circulating LH and FSH; this reaches a plateau at approximately 3 weeks with levels which are some 10 times higher than preoperative values. Alternatively, the administration of exogenous oestrogens to oophorectomized or postmenopausal women will result in rapid suppression of elevated circulating gonadotrophin levels (Figure 15.9).

The negative feedback changes result from both a direct pituitary site of action of oestradiol, with a decrease in sensitivity of the gonadotroph to GnRH (McCann et al 1974), and an action within the hypothalamus and a decrease in GnRH secretion, possibly via increased inhibitory dopaminergic and opiate activity.

The threshold for the negative feedback action of oestrogen is set to bring about suppression of gonadotrophin release with relatively small increases in oestradiol-17 β in the normal female. This negative feedback loop is the main factor which maintains the relatively low basal concentrations of plasma LH and FSH in the normal female. Circulating levels of oestradiol-17 β within the range of 100–200 pmol/l will suppress the early follicular phase gonadotrophin rise which initiates follicular development.

A negative feedback effect of progesterone on gonadotrophin secretion is now well established. Whilst progesterone, even in large doses, has little effect on baseline LH release, it can suppress the ovulatory surge of LH, as demonstrated in human females administered synthetic progestogens (Larsson-Cohn et al 1972), and oestrogen-induced positive feedback surges cannot be produced during the

luteal phase in women (Shaw 1975). The principal negative feedback action of progesterone is thus upon the midcycle gonadotrophin surge, and it may be responsible for its short 24-h duration. It also seems likely that progesterone is an important factor in the reduced frequency of gonadotrophin pulses observed during the luteal phase of the cycle compared with their frequency in the follicular phase (see below).

Positive feedback

The fact that oestrogen may stimulate (positive feedback) rather than inhibit gonadotrophin release under certain circumstances was first proposed by Hohlweg and Junkmann (1932). Their proposal has since been substantiated by numerous experimental reports in animals and humans. Under physiological conditions, the positive feedback only operates in females; it is brought about by oestrogen and appears to be an essential component in producing the midcycle ovulatory surge of gonadotrophins. Administration of oestradiol-17 β to females during the early or midfollicular phase of the cycle will induce a surge of gonadotrophins (Yen et al 1974, Shaw 1975) (Figure 15.10), but treatment with the same doses of oestrogen during the midfollicular phase induces a far greater release of LH than during the early follicular phase (Yen et al 1974). Studies on the dynamics of this positive feedback response to oestrogen, observed in greatest detail in the rhesus monkey, demonstrate an activation delay of some 32–48 h from the commencement of oestrogen administration until the onset of the positive-feedback-induced gonadotrophin surge, a minimum threshold level to be exceeded and a strength-duration aspect of the stimulus (Karsch et al 1973).

Oestrogen elicits gonadotrophin release by increasing pituitary responsiveness to GnRH and possibly by stimulating increased GnRH secretion by the hypothalamus. In the normally menstruating female, oestrogen pretreatment produces an initial suppressive action on pituitary

responsiveness (Shaw et al 1975a) followed by a later augmenting action which is both concentration and duration dependent (Shaw et al 1975a, Young and Jaffe 1976). The augmenting effect of oestrogen on GnRH pituitary responsiveness is demonstrated in Figure 15.11.

These data and others suggest that the midcycle oestrogen-induced surge of gonadotrophins may occur without the need for any increased output of hypothalamic GnRH, and indeed, this occurs in patients with endogenous GnRH deficiency receiving pulsatile GnRH treatment at a constant rate.

Progesterone by itself does not appear to exert a positive feedback effect. However, when administered to females in whom the pituitary has undergone either endogenously induced or exogenously administered oestrogen priming, progesterone can induce increased pituitary responsiveness to GnRH (Shaw et al 1975b; Figure 15.12). Since circulating progesterone levels are increasing significantly during the periovulatory period, this action may be of importance in determining the magnitude and duration of the midcycle gonadotrophin surge.

Self-Priming of the Pituitary Gonadotroph by GnRH

Results from in-vitro experiments with pituitary cells in culture indicate that GnRH is not only involved in the release of stored LH and FSH, but is of importance in maintaining the synthesis of gonadotrophins within the gonadotroph. Hence repeated exposure to GnRH of the gonadotrophin-producing cells seems essential for the maintenance of adequate pituitary stores.

Rommler and Hammerstein (1974) first demonstrated that the response to a second injection of GnRH was greater than the initial response in females, when they were retested

1–4 h following the first exposure. This response has been termed 'self-priming'.

Wang et al (1976) published more intensive studies, carried out throughout the menstrual cycle, and were able to demonstrate that self-priming had a definite cycle relationship which was greatest in the late follicular phase and around midcycle (i.e. at times of increased circulating oestrogen levels), and that oestrogen preferentially induces LH rather than FSH release (Figure 15.13).

This self-priming effect of GnRH is of importance in understanding the physiological control mechanism of gonadotrophin release. It suggests that there are two pools of gonadotrophins, one readily releasable by initial exposure to GnRH and a second reserve pool. The exposure of this larger reserve pool to GnRH allows it to be more readily released by a subsequent exposure to GnRH, and is suggestive of a transfer of gonadotrophins from one pool to the other. The stage of the cycle, i.e. the prevailing environment of endogenous sex steroids, which are the modulators, and the degree of GnRH stimulation which is the prime controller, together influence these transfer capabilities and sensitivity of the pituitary in its response to GnRH.

Pulsatile Nature of Gonadotrophin Release

The pulsatile nature of hypothalamic GnRH release is now known to determine episodic pituitary gonadotrophin secretion.

Figure 15.13 Self-priming effect of bolus injection of gonadotrophin-releasing hormone. Differing responses at different phases of the menstrual cycle. LH, luteinizing hormone; FSH, follicle-stimulating hormone.

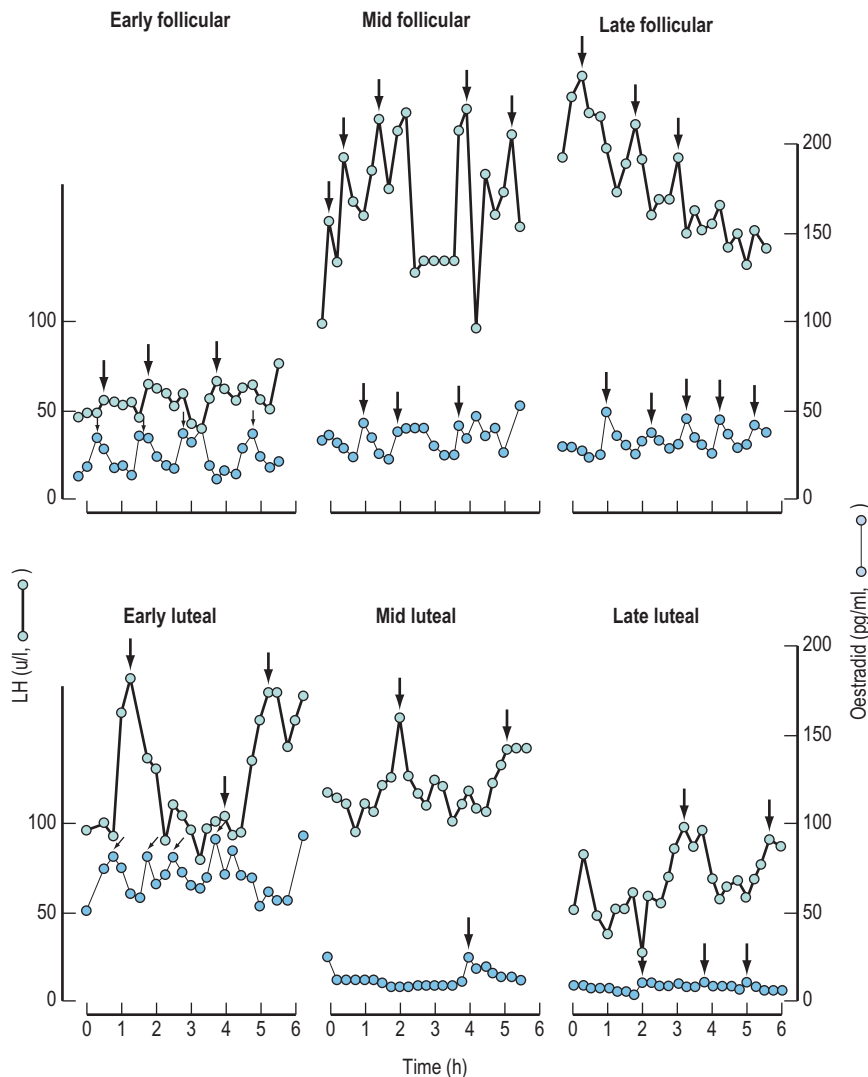

Figure 15.14 Concentrations of luteinizing hormone (LH) and oestradiol at different phases of the menstrual cycle, demonstrating different pulse frequency and amplitude.

From Backstrom CT, McNeilly AS, Leak RM, Baird DT 1982 Pulsatile secretion of LH, FSH, prolactin, oestradiol and progesterone during the human menstrual cycle. *Clinical Endocrinology* 17:29–42.

This pulsatile pattern of GnRH concentration has been reported in the pituitary stalk effluent of the rhesus monkey (Carmel et al 1976). This suggests that the pulsatile pattern of gonadotrophin release from the anterior pituitary is probably causally related to the periodic increase in the hypothalamic GnRH system.

Further support for this hypothesis is obtained from the facts that antisera to GnRH abolish the pulsatile release of gonadotrophins, and that pulsatile LH release can only be reinstated by pulsed delivery of GnRH and not by constant infusion.

Comparison of the pulsatile pattern of gonadotrophin release at different phases of the menstrual cycle demonstrates profound modulation by ovarian steroids (Figure 15.14).

In hypogonadal subjects, pulses exhibit high amplitude and high frequency with reversal of the LH:FSH ratio. However, the higher circulating level of FSH is probably not due to a higher FSH secretory rate but rather to an accumulation related to its slower clearance rate (longer half-life).

In females with normal cycles, a characteristic low-amplitude, high-frequency pulse pattern is observed during

the follicular phase. This suggests that oestrogen appears to be most effective in reducing the amplitude of gonadotrophin pulses, more markedly in FSH than LH. In contrast, the pulse pattern during the luteal phase is one of high amplitude and low frequency, probably modified by progesterone effects, on the catecholaminergic and GnRH neurone systems (Figure 15.14).

Integrative Control of the Hypothalamic–Pituitary Unit during the Menstrual Cycle

How can the complex inter-related changes in ovarian steroids and pituitary gonadotrophins that occur within each menstrual cycle be explained on the basis of our present understanding of the control of the hypothalamic pituitary unit (see Figure 15.15 for overview).

LH and FSH are released from the anterior pituitary in an episodic, pulsatile manner, and the available evidence supports a hypothalamic mechanism for this pulsatile release. Both oestradiol-17 β and progesterone can induce a positive feedback release of gonadotrophins, in many

Figure 15.15 Feedback control mechanisms in the hypothalamic–pituitary–ovarian axis. CNS, central nervous system; NA, noradrenaline; A, adrenaline; EOP, endogenous opioids; PRL, prolactin; DA, dopamine; GnRH, gonadotrophin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone.

respects comparable to that seen at midcycle, but progesterone can only produce its effect on a previously oestrogen-primed pituitary gland. There is presumptive evidence that these positive feedback stimuli also involve a direct pituitary action, with alteration in sensitivity to GnRH preceding an induced increase in hypothalamic release of GnRH.

The pattern of gonadotrophin release from the pituitary in response to repeated pulses of submaximal dose of GnRH or constant low-dose infusion over several hours suggests the presence of two functionally related pools of gonadotrophins. The first primary pool is immediately releasable, while the secondary pool requires a continued stimulus input and represents the effect of GnRH on synthesis and storage of gonadotrophins within the pituitary cell. The sizes or activity of these two pools represent pituitary sensitivity and reserve, respectively, which vary throughout the cycle and are regulated by the feedback action of ovarian steroids and by the self-priming action of GnRH itself. Oestradiol preferentially induces the augmentation of reserve and impedes sensitivity to GnRH, with a differential effect apparent for LH release. This oestradiol effect is both dose and time related.

Follicular phase

In the early follicular phase, both the immediately releasable and the reserve pool of gonadotrophins are at a minimum. The increased FSH release, responsible for initiating follicle development, must indicate an increased output of GnRH, with the lowering of negative feedback action in the presence of low levels of oestrogen and progesterone. As follicles develop, oestrogen levels rise and the negative feedback action of oestrogen on GnRH increases, suppressing FSH levels. Increasing levels of inhibin from the rapidly dividing granulosa cells of the dominant follicle further suppress FSH secretion at a pituitary level.

With these progressive increases in oestradiol throughout the midfollicular phase, the quantitative estimates of the primary, immediately releasable, pool of gonadotrophins increase slightly, whilst the reserve pool increases greatly, thus demonstrating the augmentation action of oestradiol primarily upon the reserve pool. Since there is no marked increase in circulating gonadotrophin levels during this phase, secretion of GnRH must be minimal or else there is evidence of impedance of GnRH sensitivity by oestrogen.

Mechanism for preovulatory gonadotrophin surge

During the late follicular phase, there is an increase in the amount of oestradiol secreted by the ovary. Under this influence, the sensitivity of the gonadotroph to GnRH eventually reaches a phase when GnRH can exert its full self-priming action. The consequence is the transference of gonadotrophins from the secondary reserve pool to the releasable pool. The increased pituitary responsiveness to GnRH may be further enhanced by the slight progesterone rise which can affect its action on a fully oestrogen-primed anterior pituitary. These changes culminate in the production of the ovulatory gonadotrophin surge. It is possible that these events could occur even if the gonadotrophs were exposed to a constant level of GnRH. However, an increased secretion of GnRH, as reported in rhesus monkeys and rats (Sarker et al 1976), at midcycle, which would act synergistically with the changes in pituitary sensitivity, also seems likely in the human.

The LH and FSH surges begin abruptly (LH levels doubling over 2 h) and are temporarily associated with attainment of peak oestradiol-17 β levels. The mean duration of the LH surge is 48 h, with an ascending limb of 14 h which is accompanied by a decline in oestradiol-17 β and 17-hydroxyprogesterone concentrations but a sustained rise in inhibin levels.

The ascending limb of LH is followed by a peak plateau of gonadotrophin levels lasting some 14 h and a transient levelling of progesterone concentrations. The descending limb is long, lasting approximately 20 h, and accompanying this is a second rise in progesterone, a further decline in oestradiol-17 β and 17-hydroxyprogesterone, and a rise in inhibin levels.

The concentration of inhibin during the periovulatory interval is not correlated with oestradiol-17 β or progesterone changes. It may merely reflect the release from follicular fluid of stored inhibin.

Ovulation occurs 1–2 h before the final phase of progesterone rise or 35–44 h from the onset of the LH surge.

Luteal phase

The significantly lower basal gonadotrophin secretion in the face of high pituitary capacity during the midluteal phase suggests that endogenous GnRH should be very low.

A progressive decrease in sensitivity and reserve characterizes pituitary function during the late luteal phase and into the early follicular phase of the next cycle. This is probably due to a progressive decline in oestrogen and progesterone on which sensitivity and reserve are dependent. The role played by the proposed ovarian inhibin on preferentially

controlling FSH secretion has still to be completely determined.

It is therefore apparent that the functional state of the pituitary gonadotroph as a target cell is ultimately determined by the modulating effect of ovarian steroid hormones via their influence on the gonadotroph's sensitivity and reserves, and upon the hypophysiotrophic effect of GnRH.

With such a complex inter-related control mechanism, it is perhaps not surprising that many drugs which affect neurotransmitters, ill health or associated endocrine disorders can disrupt normal hypothalamic–pituitary–ovarian function, resulting in disordered follicular growth and suppression of ovulation and in severe cases cause amenorrhoea.

KEY POINTS

1. The unique portal blood supply to the pituitary gland provides the basis of hypothalamic regulation of the pituitary secretion. It also explains the vulnerability of the gland to hypotension.
2. GnRH, secreted by neurones of the hypothalamus into the portal system, controls the release of both FSH and LH, with ovarian sex steroids playing a role in modulating the proportions of each hormone secreted.
3. The final step in the release of stored LH and FSH, and subsequent induction of further biosynthesis of both hormones following GnRH stimulation, involves Ca^{2+} , protein kinase C and cAMP.
4. The control of GnRH secretion is highly complex and depends upon a number of inhibitory (dopamine, endorphins) and excitatory (noradrenaline, prostaglandins) neurotransmitters, and is modulated by various other substances such as activin, inhibin and follistatin.
5. The response of the pituitary gland to exogenous GnRH depends upon the ovarian sex steroid environment prevailing and the degree of GnRH stimulation. Prolonged exposure to GnRH produces downregulation of LH release, which is used pharmacologically to induce a state of hypogonadotrophic hypogonadism to treat many ovarian-steroid-hormone-dependent disorders.

Introduction

Amenorrhoea and oligomenorrhoea are symptoms of ovarian and reproductive dysfunction. Patients thus commonly present to the gynaecologist with complaints of problematic menstruation or fertility delay. This chapter provides an overview of the current understanding and general management of the associated disorders of the hypothalamic–pituitary–ovarian (HPO) axis that result in amenorrhoea and oligomenorrhoea. These symptoms are also features of the polycystic ovary syndrome (PCOS), and a detailed description of the symptoms, diagnosis and management of PCOS is provided in Chapter 18.

Definitions

Normal menstruation

Regular monthly menstruation is a phenomenon of modern society. Furthermore, the availability of effective contraception has enabled couples to choose both the size and timing of their desired family. The classic data (derived from 22,754 calendar years of experience) from the studies of Treloar et al (1967) demonstrated that each woman has her own central trend and variation in menstrual cycle length, both of which change with age (Figure 16.1). The first (and last) few years of menstrual life are marked by a variable pattern of mixed short and long intervals, with a characteristic transition into and out of the more regular pattern of middle life (Figure 16.2). The length, regularity and frequency of normal menstrual cycles have been described in both population and observational studies (Harlow and Ephross 1995, Fraser and Inceboz 2000). Mean menstrual cycle length between the ages of 20 and 34 years varies between 28 and 30.7 days

(range 19.7–43.5 between the 5th and 95th centiles). Physiologically regular menses indicate cyclical ovarian activity, in turn dependent upon an intact HPO axis. Aberrations in menstrual pattern are thus an indication of disorder of ovarian function. The average age of the menarche is 12.8 years, but this has been gradually decreasing. Factors such as ethnic origin, socio-economic status and nutrition can affect age of menarche. With obesity presently such a prominent problem, it is interesting to note that there is a relationship between age of menarche and body mass index (BMI), with early menarche associated with raised BMI (Golden and Carlson 2008).

Amenorrhoea

Amenorrhoea is complete absence or cessation of menstrual bleeding for more than 6 months (not due to pregnancy). Primary amenorrhoea is defined as no spontaneous onset of menstruation by the age of 16 years. Secondary amenorrhoea is defined as the absence of menstruation for 6 months or longer if the patient has previously experienced regular menses, and for 12 months or more when a patient has oligomenorrhoea. The menopause is a retrospective diagnosis, defined as 12 months of amenorrhoea. If there is any clinical confusion, serum follicle-stimulating hormone (FSH) may be checked (>30 U/l on two separate occasions, 6 months apart).

Oligomenorrhoea

Oligomenorrhoea is a reduction in the frequency of menstruation where menstrual intervals may vary between 6 weeks and 6 months. It is important to note, however, that regular menstrual cycles every 6 weeks are usually indistinguishable from normal shorter interval cycles in terms of

follicular growth and hormone production. Oligomenorrhoea may therefore include a spectrum of conditions ranging from virtual normality at one end to the same causes as amenorrhoea at the other. The main difference appears to be in the frequency of polycystic ovaries, which ultrasound and endocrine studies show to account for approximately 90% of cases of oligomenorrhoea and 33% of cases of amenorrhoea.

Causes of Amenorrhoea

Causes of amenorrhoea are classified according to a systematic endocrine approach and are listed in Box 16.1 (Baird 1997). Disorders in other endocrine systems, such as thyroid disease and adrenal disease, may result in amenorrhoea.

Physiological amenorrhoea

Amenorrhoea is physiological at certain critical times in a woman's life, these being prepuberty, during pregnancy and lactation, and in the postmenopausal period. Amenorrhoea, if not physiological, has an estimated prevalence in the female population of reproductive age of 1.8–3% (Pet-

tersson et al 1973). Amenorrhoea may be either primary or secondary. The prevalence of secondary amenorrhoea is in the order of 2–5% (Singh 1981). The aetiology of primary and secondary amenorrhoea may be similar. Causes of primary amenorrhoea are listed in Box 16.2. In practice, investigation of primary amenorrhoea is usually initiated by the age of 14 years if there is evidence of delayed puberty (absent secondary sexual characteristics and absent menses), or no menstruation within 4 years of the onset of adrenarche and thelarche (Zreik and Olive 1998). The diagnosis of cause of primary amenorrhoea may be categorized depending on whether or not the uterus is present, and whether or not there is breast development. Zreik and Olive (1998) described a very useful scheme to aid diagnosis of primary amenorrhoea (Figure 16.3).

Anatomical causes

Anatomical abnormalities of the genital tract account for approximately 1% of cases of amenorrhoea. The anatomical causes of amenorrhoea are summarized in Box 16.3. In girls with breast development but evidence of an absent uterus, two disorders need to be considered. First, congenital absence of the uterus (Müllerian agenesis, Mayer–Rokitansky–Kuster–Hauser syndrome) is due to an early development failure of the Müllerian system. Affected girls have a normal XX karyotype, normal ovaries and secondary sexual characteristics. The vagina is absent or hypoplastic. Magnetic resonance imaging is a useful adjunct diagnostic test for establishment of the diagnosis, thereby avoiding laparoscopy. Since anomalies of the Wolffian duct system may be present in these patients, an intravenous urogram is an important investigation for this condition. The second disorder to consider is testicular feminization or androgen insensitivity, an X-linked inherited disorder. Patients have a 46XY karyotype, a female phenotype and undescended testes. The uterus is absent and there is a short, blind vaginal pouch. The X-linked androgen receptor is essential for androgen action, leading to normal primary male sexual development prior to birth (masculinization). Thus, androgen receptor dysfunction in XY individuals results in androgen insensitivity syndrome. Diagnosis of this syndrome is established on clinical findings, endocrine investigations and, if possible, family history. There are three phenotypes: complete androgen insensitivity syndrome (CAIS), partial androgen insensitivity syndrome (PAIS) and mixed androgen insensitivity syndrome (MAIS). CAIS is most often diagnosed on clinical findings and laboratory investigations,

and PAIS and MAIS usually require a family history consistent with X-linked inheritance (Gottlieb et al 1999). Androgen insensitivity may be caused by several mutations of the androgen receptor (Gottlieb et al 1999), resulting in a lack of androgenization during sexual differentiation (Imperato-McGinley 1995). Development of the uterus and upper vagina is inhibited, as the secretion of anti-Müllerian hormone (AMH) by the testes is normal in these patients. Recently, due to nationwide cooperation between paediatric endocrinologists in the UK, an extensive database (278

cases) of phenotypic features, androgen receptor binding, and mutational analysis of cases of intersex and ambiguous genitalia has been established (Ahmed et al 2000). All cases of PAIS presented within the first month of life. The median age for presentation of individuals with CAIS was 1 year. The gonads were removed before puberty in 66% of cases with CAIS, and after puberty in 29% of cases. The indication for gonadal removal is the high incidence of neoplasia (5%).

A further anatomical cause of primary amenorrhoea is the presence of an imperforate hymen that obstructs the outflow of menses. Girls commonly present with cyclical pelvic pain and a delayed menarche. Secondary amenorrhoea can result from anatomical abnormalities; the endometrium may be destroyed as a result of infection (e.g. pelvic tuberculosis) or iatrogenically, as a result of an endometrial ablation procedure. Complications of uterine curettage can also result in amenorrhoea. An example of this is Asherman's syndrome (Asherman 1948), which is defined by the presence of intra-uterine permanent adhesions, obliterating the uterine cavity either partially or completely. The main cause of this syndrome is the procedure of endometrial curettage required to treat secondary postpartum haemorrhage due to retained placental products. It has also been suggested that missed miscarriages are an important risk factor for the development of adhesions.

Hypothalamic–pituitary dysfunction (endocrine causes)

The hypothalamic–pituitary axis is regulated at two levels. At a higher level, gonadotrophin-releasing hormone (GnRH) neurones within the hypothalamus are stimulated by afferent inputs from the central nervous system. Furthermore, there is endocrine control of GnRH synthesis and secretion

by means of gonadal feedback mechanisms and GnRH itself. At a lower level, the output of FSH and luteinizing hormone (LH) by the gonadotropes in the anterior pituitary reflects GnRH activity. Gonadotrophin synthesis and secretion are, in turn, influenced by endocrine feedback from the ovaries as well as paracrine mechanisms and other extrinsic factors. Endocrine causes of oligomenorrhoea and amenorrhoea include disorders of the HPO axis that are summarized in Box 16.4. Disturbances in menstrual pattern will be the consequence of either a structural or functional defect in the tightly controlled feedback system involving the hypothalamus, anterior pituitary and ovary (Baird 1997; Figure 16.4). If the uterus is present and there is no breast development, absence of menstruation may be due to failure of secretion of GnRH or to failure of pituitary or gonadal function (see Figures 16.3 and 16.4). Hypothalamic amenorrhoea suggests an intact HPO axis.

Kallman's syndrome

Kallman's syndrome, occurring in 1:50,000 girls (Kallman et al 1944), has the associated symptom of anosmia and is

an inherited autosomal-dominant or X-linked autosomal-recessive anomaly. The impairment of olfactory sensation is often subtle. Women with this condition typically present with primary amenorrhoea and poor development of secondary sexual characteristics. If untreated, infertility results. The gonadotrophin deficiency is due to an inability to activate pulsatile GnRH secretion (Leiblich et al 1982). Five Kallman's syndrome genes have been identified to date. The syndrome appears to result from insufficient cell signalling through fibroblast growth factor receptor 1 (FGFR1), in which integrins play a role in signalling, and the prokineticin receptor 2, a G-protein coupled receptor essential for normal development of the olfactory bulbs and sexual maturation (Abreu et al 2008). Some cases are due to a mutation in the *KAL* gene situated on the p22.3 region of the X chromosome (tip of the short arm) that codes for an adhesion-molecule-like X chromosome (Legouis et al 1991). This protein has homology with fibronectin and plays a role in the migration of GnRH-like neurones from the nasal pit to the hypothalamus (Rugarli and Ballabio 1993). *KAL1* gene mutations account for 33–70% of cases of the X-linked form of Kallman's syndrome. Ovulation induction can achieve pregnancy for these women, but requires both exogenous FSH and LH to successfully stimulate follicular maturation and ovarian steroidogenesis.

Hypogonadotrophic hypogonadism

Female hypogonadism refers to deficient or abnormal function of the HPO axis that clinically presents with menstrual cycle disturbances. Female hypogonadism can be due to a congenital or acquired cause, and the defect can be at the level of the hypothalamus, pituitary or ovary. It is characterized by reduced secretion of FSH (although this can be

normal) and LH. There is a consequent failure of follicular development and oestradiol production by the ovaries. A hypo-oestrogenic state thus prevails. If the situation is present before puberty, the girl will present with primary amenorrhoea and a lack of secondary sexual features. Usually, no organic lesion is identified in the hypothalamus or anterior pituitary, and the situation is considered to be idiopathic. Mutations in three genes account for 15–20% of all cases of idiopathic hypogonadotrophic hypogonadism: *KAL1*, *GNRHR* and *FGFR1*. Nearly all mutations are point mutations (Pederson-White et al 2008). Severe weight loss, psychological stress and chronic debilitating disease are all associated with a cessation of hypothalamic function, and are conditions that will be addressed later.

Hypothalamic and pituitary lesions

The most likely hypothalamic lesion to present to a gynaecologist is a craniopharyngioma. Compression of the hypothalamus will suppress GnRH secretion and interrupt portal flow of GnRH in the pituitary stalk. The peripubertal period is the most common age for presentation. The lesions are cystic and often calcified, and are readily recognizable on a lateral skull radiograph or with imaging techniques, such as magnetic resonance imaging. Other tumours which may affect hypothalamic–pituitary function are gliomas (which may arise from the optic tract), meningiomas, endodermal sinus tumour (yolk sac carcinoma), which secretes α -fetoprotein, and congenital hamartomas composed of GnRH neurosecretory cells which can lead to precocious puberty (Yen 1999). Congenital absence of the anterior pituitary gland along with other midline structural defects is extremely rare. Primary deficiency of pituitary hormone secretion is also very uncommon. Growth hormone deficiency may occur in isolation or with panhypopituitary dwarfism. Pituitary failure may be secondary to other organic disease, such as pituitary adenoma, mumps, encephalitis, infarction (Sheehan's syndrome, secondary to major obstetric haemorrhage) and irradiation. Pituitary cells are relatively resistant to irradiation compared with other brain tissues that are more radiosensitive. Disturbance of pituitary function may therefore be indirectly due to hypothalamic damage. Subjects with gonadal failure are oestrogen deficient and have elevated gonadotrophins (hypergonadotrophic hypogonadism). Causes of gonadal failure are listed in Box 16.5 and will be addressed in detail later. One of the most common chromosomal causes of primary amenorrhoea is Turner's syndrome. Enzyme-deficiency states associated with primary amenorrhoea include galactosaemia and 17-hydroxylase deficiency.

Central nervous system–hypothalamic disturbance

The modulating influence of extrahypothalamic brain centres on the pulsatile nature of hypothalamic GnRH secretion is addressed in Chapter 15. Psychological disorders account for approximately one-third of cases of amenorrhoea due to central nervous system–hypothalamic disturbance. Functional disorders of the hypothalamic–pituitary axis that cause amenorrhoea result from weight loss, extreme exercise and psychological stress. In each of these situations, there is

Figure 16.4 The hypothalamic–pituitary–ovarian–uterine axis. GnRH, gonadotrophin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; A, inhibin B; B, Antimüllerian hormone. Adapted with permission from Baird DT 1997 *The Lancet* 350: 275–279. ©The Lancet Ltd 1997.

a decrease in GnRH neuronal activity in the hypothalamus with a subsequent decrease in gonadotrophin secretion (FSH and LH). Ovarian follicular development and ovulation fail to occur if LH pulsatility is less frequent than every 2 h (Baird 1997).

Weight-related amenorrhoea

Marked weight loss, such as that occurring with anorexia nervosa, may result in amenorrhoea. However, menstrual irregularity is an associated feature of all eating disorders rather than being restricted to anorexia nervosa alone. The amount of weight loss that may result in cessation of menstruation varies from a few kilograms in an adolescent who is dieting to a loss of up to 50% of body weight in women with anorexia nervosa (Warren 1995). Regular menses are unlikely to occur in subjects with BMI <19 kg/m² (Balén et al 1995). It has been reported that nearly one-fifth of the body mass should be adipose tissue for ovulatory cycles to be sustained (Frisch 1984). The rate of loss of weight

seems to be important, and rapid loss is frequently associated with psychological disturbance. The chronic hypo-oestrogenic state that becomes established in long-standing amenorrhoea carries significant risk of premature osteoporosis and cardiovascular disease. Irregular cycles and anovulation are also common in PCOS and may be due to the commonly associated raised BMI. The insulin resistance with PCOS which is exacerbated by an increase in BMI affects the intraovarian response to gonadotrophins (Greer et al 1980).

Exercise-related amenorrhoea

Irregularities of menstrual pattern are reported in association with many competitive sporting activities. There is typically a progressive failure of regular menses with anovulatory cycles and amenorrhoea and, in prepubertal girls, a delayed menarche. Usually, the degree of menstrual aberration reflects the intensity and length of sporting activity (Yen 1999). Secondary amenorrhoea and oligomenorrhoea are

also common in professional dancers (Warren et al 1986). Women with hypothalamic amenorrhoea associated with an excessive exercise habit, weight loss and stress have hypercortisolism, on account of raised corticotrophin-releasing hormone (CRH) and adrenocorticotrophic hormone. Consequently, there is likely to be disruption of reproductive function as CRH directly inhibits GnRH secretion, possibly via increased endogenous opioid secretion (Speroff et al 1999a). A detailed study was reported by Laughlin and Yen (1996) which addressed the interactions between energy balance and regulators of metabolic fuel and the association with reduced LH pulsatility in women with exercise-induced menstrual dysfunction. Notable differences were observed in nutritional intake, insulin/glucose dynamics, the somatotrophic axis and LH pulsatility with both degree of exercise and menstrual pattern. Those athletes who were amenorrhoeic demonstrated an increase in insulin sensitivity and a reduced hypoglycaemic effect of insulin-like growth factor 1 (IGF-1), along with raised growth hormone and cortisol concentrations. The authors suggest that there is a cascade of glucoregulatory adaptations designed to redistribute metabolic fuel and thereby conserve protein. Furthermore, the reduced GnRH/LH pulse generator activity is in response to both a reduced stimulatory effect of IGF-1 (due to increased IGF-binding protein 1) and central negative effects of corticotrophin-releasing factor. The outlook for women with stress/exercise-related amenorrhoea is very good if recognized early. Most women see a return of ovulatory cycles with weight gain or reduction in levels of stress or exercise habit (Speroff et al 1999a). Hormone replacement may be

indicated for women with long-standing hypothalamic amenorrhoea as there will be a risk of bone loss and cardiovascular changes.

Metabolic hormones regulating reproductive function

Kisspeptins, and their cognate receptor gpr-54, were first found to regulate the hypothalamic–pituitary–gonadal axis in 2003, when two groups demonstrated that mutations in gpr-54 cause idiopathic hypogonadotropic hypogonadism characterized by delayed or absent puberty (Roseweir and Millar 2009). KiSS1 neurones have recently been suggested to mediate leptin's effect on the reproductive system by encoding hypothalamic neuropeptides. Leptin is the primary product of the *ob* gene and is a 167 amino acid peptide made exclusively in adipose tissue; it acts on the hypothalamus. It is likely that leptin plays a central role in energy production, reproduction and weight, and it has been proposed as a mediator between adipose tissue and the gonads (Matkovic et al 1997). In both eating disorders and excessive exercise, amenorrhoea results from an adaptive response to an energy deficit, partially mediated by leptin. A critical blood leptin level has been reported as necessary to trigger reproductive function in women, suggesting a threshold effect. In this context, severe weight loss is known to result in subnormal gonadotrophin concentrations. Leptin receptors have been identified in the hypothalamus, and leptin inhibits neuropeptide Y (NPY) synthesis and release. A link between leptin and GnRH neurones is, in part, mediated by NPY. Secondary leptin deficiency can present as weight-related amenorrhoea in women (Conway and Jacobs 1997). Speroff et al (1999a) noted that CRH is elevated in stress- and, particularly, weight-loss-related amenorrhoea. It has been proposed that the decrease in leptin and increase in NPY described in stress-related weight loss are inadequate to suppress the stress-induced increase in CRH. Moreover, the increase in CRH and resulting hypercortisolism exacerbate the increase in metabolism and weight loss. Research leading to a better understanding of the metabolic regulation of reproductive function has implications for the prevention and management of reproductive dysfunction and its associated comorbidities.

Neurological and psychiatric disorders

Epilepsy, bipolar disorder and migraines are common disorders which can be associated with disturbances in menstrual function in adolescent girls. With epilepsy, it is thought that both the disease itself and the treatment medications contribute to the aetiology of the menstrual abnormality by disturbing the HPO axis. Many antipsychotic drugs are also dopamine antagonists, and can cause prolactin levels to increase up to 10-fold, again resulting in inhibition of the HPO axis (see Box 16.6).

Chronic illness

A variety of mechanisms in chronic illness can result in pubertal delay and cessation of menses. These include

changes in nutrition, behaviour, metabolism, hormone balance, associated stress and medications.

Idiopathic delayed puberty

The limiting factor for increasing amounts of gonadotrophin secretion as normal puberty approaches is hypothalamic GnRH release (Yen 1999). Delayed puberty may be recognized by the age of 14 years if breast development is still absent. Most cases are due to idiopathic hypothalamic failure and usually resolve spontaneously. There may often be a family history of late puberty. Enquiry should seek any history of impaired olfaction, marked weight loss, extremes of exercise and ill health. Other causes of amenorrhoea with oestrogen deficiency should be excluded with a lateral skull radiograph/hypothalamic-pituitary imaging (non-endocrine tumours, e.g. craniopharyngioma), and serum prolactin (prolactinoma) and FSH measurements (ovarian dysgenesis). If the diagnosis is idiopathic delayed puberty, it remains difficult to distinguish whether the failure is purely delayed or permanent, and thus treatment should commence without delay. Once the patient's secondary sexual characteristics are mature, treatment may be periodically interrupted to establish whether there is spontaneous HPO activity.

Hyperprolactinaemia

In girls with primary amenorrhoea with normal breast development and a uterus, hyperprolactinaemia must be considered. Approximately 15–20% of women with secondary amenorrhoea have elevated serum prolactin concentrations (Jacobs et al 1976). Unlike the other trophic hormones secreted by the anterior pituitary, prolactin secretion is regu-

lated primarily by inhibition from the hypothalamus by dopamine. Prolactin secretion is not subject directly or indirectly to negative feedback by peripheral hormones. Regulation of secretion is via a short-loop feedback on hypothalamic dopamine by means of a countercurrent flow in the hypophyseal portal system (as well as inhibition of GnRH pulsatile secretion). Prolactin secretion is stimulated by peripheral oestrogen, and this is derived from the placenta in pregnancy.

Circulating concentrations of prolactin rise during pregnancy; at term, the levels are four to 20 times higher than those in non-pregnant women. After delivery, prolactin levels decline in non-lactating women over a 15–20-day period. In lactating women, circulating levels of prolactin are maintained by suckling, and hyperprolactinaemia may last for up to 2 years. During breastfeeding, there is an increase in the sensitivity of the HPO axis to the negative feedback effect of oestradiol (Illingworth et al 1995). The duration and causes of this period of hypersensitivity to oestrogen are unknown. Data are available to support the concept that the suckling-induced suppression of the GnRH system during lactation is associated with enhancement of the negative effects of oestradiol on the hypothalamic GnRH system (Perheentupa et al 2000). Pathological hyperprolactinaemia is associated with amenorrhoea. There is no ovarian function, reduced or absent pulsatility of LH secretion, and an absence of positive feedback response to oestrogen. Treatment of raised prolactin concentrations restores ovulation in 80–90% of women (Randeve et al 2000), and normal cyclical activity returns once prolactin levels are reduced. Pathological hyperprolactinaemia may be induced by drugs that inhibit dopamine action or production. A list of potential compounds is given in Box 16.6. Pharmacological agents account for 1–2% of cases (see Box 16.6). The most common causes of hyperprolactinaemia are pituitary prolactinomas (40–50% of cases) and idiopathic hypersecretion. Primary hypothyroidism will be the coincident diagnosis in 3–5% of cases. Rare causes are ectopic production from a distant extrapituitary tumour, and chronic renal failure may be associated with hyperprolactinaemia, due to both decreased excretion of the hormone and central mechanisms affecting dopamine secretion. Only about half of patients who present with hyperprolactinaemia describe galactorrhoea. Moreover, only about half of the women who report galactorrhoea have raised prolactin levels (Baird 1997). Serum prolactin measurements are essential. Usually, a second sample is required if the first is raised. A common problem is the misinterpretation of the upper normal limit of a geometric (skewed) distribution of normal values. The upper limit is taken at approximately 800 mU/l. The functional relevance of borderline hyperprolactinaemia is unclear. It is most important to consider the prolactin concentration in the context of the associated ovulatory disorder. Significant hyperprolactinaemia is usually associated with oligomenorrhoea or amenorrhoea. Mild hyperprolactinaemia is identified with some cases of PCOS. The phenomenon is likely to be the consequence of excess oestrogenic stimulation. Conversely, prolactin levels are low in hypothalamic amenorrhoea and are likely to be due to lack of oestrogenic stimulation. Thyroid-releasing hormone stimulates prolactin. This can be raised in hypothyroidism,

so thyroid function tests should be checked in hyperprolactinaemia. In addition, serotonin can increase prolactin with resulting possible effects from the use of drugs such as selective serotonin reuptake inhibitors.

The mechanism by which hyperprolactinaemia interferes with ovarian function is not clearly defined. It has been suggested that in hyperprolactinaemia, endogenous opioids may have an inhibitory effect on hypothalamic GnRH-secreting neurones (Grossman et al 1982). However, this is not a consistent observation, and prolactin may, in fact, have a direct effect on hypothalamic activity. Although serum levels of prolactin in women with idiopathic hyperprolactinaemia or with pituitary tumours may normalize after treatment with a dopamine agonist (or after pituitary surgery), there are many issues about treatment and long-term follow-up that remain unresolved. Recently published guidelines have advised that the minimal length of dopamine agonist therapy should be 1 year (Casanueva et al 2006). A recent report indicates that dopamine agonists can be safely withdrawn in patients with long-term normalization of prolactin levels and no evidence of tumour on magnetic resonance imaging (Colao et al 2003). The natural history of hyperprolactinaemia is not known. Interestingly, as many as 10% of patients may have a spontaneous remission (Glasier et al 1987). In a longitudinal prospective 3–7 year study of 30 women with untreated hyperprolactinaemia, with annual clinical, radiographic and hormonal evaluation, progression of the disease was observed to be unlikely; in fact, some women showed clinical and radiographic improvement (Schlechte et al 1989).

Ovarian failure

It is well established that the number of follicles in the human ovary declines steadily from midlife onwards. The onset of menopause is prompted by the number of ovarian follicles falling below a critical number as the consequence of the programmed disappearance of a limited store of follicles. The process is irreversible as oogonial stem cells disappear after birth. The loss of follicles is age dependent, and the rate of disappearance increases with age. There is a reported acceleration of loss from the age of 37.5 years (Faddy et al 1992). In this context, Richardson et al (1987) observed that entry into the perimenopausal phase of life was associated with a marked decline in follicle reserve, and that the reserve of follicles was nearly exhausted as menopause approached.

Premature ovarian failure (POF), or more appropriately primary ovarian insufficiency, is defined as the triad of amenorrhoea, oestrogen deficiency and elevated concentrations of FSH and LH in women less than 40 years old. It also includes women with primary amenorrhoea; that is, those who have no known prior ovarian function. Secondary ovarian failure occurs in women who have previously menstruated. The causes of both are similar. In patients diagnosed with POF, particularly with a recent diagnosis or a fluctuating FSH, there has been a reported pregnancy rate of 5–10% (van Kasteran and Schoemaker 1999). For those less fortunate, oocyte donation is a possible alternative.

The age that best separates 'premature' from 'normal' menopause is arbitrary. The definition of POF assumes that

those patients with the disorder constitute a group with specific characteristics that distinguish them from patients with normal menopause (Alper et al 1986). Forty years is the preferred age for definition for practical purposes. Many women with POF at 40 years or younger are concerned with fertility. If one were to define abnormality as those values greater than, or less than, two standard deviations (SD) from the mean (where 95% of the observations of a normally distributed variable are found), then 40 years is also an appropriate age. If the age of menopause is assumed to be a normally distributed variable, Walsh (1978) reported the mean age of menopause as 50.4 years (SD 3.72 years), and 2.5% of women reach menopause at 43 years of age or younger. There are no unique features that unequivocally establish the diagnosis of POF. Indeed, the diagnosis of POF is often delayed, even with the classic symptoms of menopause. At least 4 months with missing or irregular periods may indicate carrying out a serum FSH which, if elevated in the menopausal range on at least two occasions a few weeks apart, is a useful diagnostic test; ultrasound and ovarian biopsy have no role. A delay in diagnosis may result in preventable bone loss (Neale 2009). Ovarian failure itself is an irreversible pathological process with major implications for the patient (in particular, reduced bone mineral density, increased cardiovascular risk and infertility), and thus its diagnosis is an important responsibility for the gynaecologist.

The incidence of POF is not precisely known. Calculations based on the incidence of permanent secondary amenorrhoea suggest 2–3% (Bachmann and Kemmann 1982). Coulam et al (1986) reported POF in 1–3% of the general population. These latter authors conducted a detailed assessment of age-specific incidence rates of natural menopause for a cohort of 1858 women during a 4-year period, and identified a 1% risk at 40 years of age. The incidence at 30 years of age is 0.1% and decreases as age decreases (Anasti 1998). As such, the condition is not rare.

Advances in modern molecular biology have enabled major contributions to be made to understanding the aetiology of POF; however, despite this, only one-third of women have an identifiable pathology (Conway 1997). POF indicates absent ovarian function; it is not a disease but a clinical state and is often a fluctuating condition. Ovarian failure may be primary or secondary, and the chromosomes of the patient may be normal or abnormal. Common causes of POF are summarized in Box 16.5. Genetic disorders are the most common identifiable causes. Chromosomal anomalies are found in women with primary amenorrhoea and ovarian dysgenesis. In Turner's syndrome, there is an X chromosome deletion. Typically, these patients have streak ovaries, are of short stature and have a characteristic phenotype, including one or some of the following features: neck webbing, widely spaced nipples, increased carrying angle and coarctation of the aorta. Approximately two-thirds of Turner's patients have the total loss of one X chromosome, and the rest either exhibit a structural abnormality in one X chromosome or display mosaicism with an abnormal X chromosome (Speroff et al 1999b). Menstrual function and pregnancy are possible among patients with XO mosaicism. In Turner's girls, 10–20% experience spontaneous puberty and 2–5% experience spontaneous menstruation (Pasquino et al 1997). Girls

with ovarian dysgenesis may be grouped according to their karyotype (Speroff et al 1999c). Fifty percent of girls will have Turner's syndrome and 25% will be mosaics (45X/46XX). Patients may have gonadal dysgenesis and a normal XX chromosome complement (25%). This is pure gonadal dysgenesis and the girls invariably have streak ovaries (Sohval 1965), diagnosis of the latter only being made after direct visualization, usually at laparoscopy. In XY gonadal dysgenesis, the testis fails to develop due to loss or mutation of the sex-determining region of the Y chromosome (Tdy or SRY). The testis-determining gene, *Tdy*, is situated on the short arm of the Y chromosome, and the gene responsible for the H-Y antigen is on the long arm (Goodfellow and Lovell-Badge 1993). If an XY karyotype is detected, the gonadal streaks should be removed since there is a risk of neoplastic transformation. Recent attention has focused on other genetic determinants of POF. Gonadotrophin resistance as a consequence of an FSH receptor mutation has been described (Aittomaki et al 1995). It has been known for some time that fragile X mental retardation 1 gene (*FMR1*) is characterized by a dynamic CGG repeat expansion in the 5' untranslated region. Female carriers of the *FMR1* premutation allele are at risk of passing the *FMR1* full mutation (>200 repeats) to their offspring, resulting in mental retardation known as fragile X (De Caro et al 2008). This is the most common inherited form of mental retardation. Women who carry one X chromosome with a fragile X premutation display an increased prevalence of POF (Conway et al 1995). This is estimated to be approximately 15–24% compared with the incidence of 1% in the general population. The US National Society of Genetic Counselors does not currently recommend routine testing of minors for the *FMR1* premutation allele. There is ongoing discussion regarding the most appropriate terminology to describe the reproductive abnormalities associated with the *FMR1* mutation, sometimes known as fragile X-associated primary ovarian insufficiency.

It is felt that the term 'primary ovarian insufficiency' may be preferable to 'POF' as it better describes what is, in fact, a spectrum of ovarian changes rather than what is sometimes not complete dysfunction of the ovary. Family history remains a predictor of early menopause. In a case-control study of 344 cases of early menopause, a family history of earlier menopause (before 46 years) was associated with an increased risk of early menopause, with the link being strongest in women with a history of menopause before 40 years of age (Cramer et al 1995). Within the last few years, a mutation in the *FOXL2* gene, located on chromosome 3 and essential for proper reproductive function in females, has been implicated in POF (Crisponi et al 2001). The authors indicate that this is the first human gene to be identified that may play a role in the maintenance of ovarian follicles. Those carrying mutations in *FOXL2* display blepharophimosis/ptosis/epicanthus inversus syndrome, an autosomal-dominant disease associated with eyelid defects and POF. It is quite remarkable that *FOXL2* encodes a protein important to both eye and ovarian development. *FOXL2* mutations and other gene mutations will only account for a small fraction of cases of POF, but the identification of genes regulated by *FOXL2* will contribute to understanding of the biochemical pathways that may be

aberrant in POF, and hence potentially offer novel treatments for female infertility in the future. Another gene thought to be related to POF is *BMP15*. Recent studies have demonstrated heterozygous *BMP15* missense mutations in women with POF. Patients with galactosaemia treated in early life with a galactose-free diet exhibit a high frequency of ovarian failure. Affected individuals have mutations of the *galactose 1-phosphate uridylyltransferase* gene (Kaufman et al 1981). The associated feature of ovarian failure is considered to be a consequence of accumulated galactose disturbing the migration of the germ cells from the urogenital ridge to the gonad in fetal life. There is an association between autoimmune disease and ovarian failure, and between 10% and 20% of women with POF have intercurrent autoimmune conditions (Conway et al 1996). These include Addison's disease, hypothyroidism, pernicious anaemia, Hashimoto's disease, idiopathic thrombocytopenia, rheumatoid arthritis with vitiligo, alopecia areata, Cushing's disease, autoimmune haemolytic anaemia and myaesthesia gravis. Among patients in whom the aetiology of POF is obscure, there are other lines of evidence to suggest autoimmune mechanisms. Circulating antibodies to ovarian tissue have been demonstrated in the sera of women with POF. Organ-specific autoimmunity may be directed against the intracellular enzymes involved in hormone production. 3- β -hydroxysteroid dehydrogenase (3- β -HSD) has been identified as an autoantigen in one-fifth of women with POF. This observation now offers a potential marker for autoimmune ovarian damage, although the presence of anti-3- β -HSD antibodies may be the consequence of ovarian inflammation rather than the causal antigen (Arif et al 1996). Infections associated with loss of ovarian function are mumps and pelvic tuberculosis. Environmental factors contributing to an early menopause include cigarette smoking. As a consequence of the improved survival for patients with certain neoplastic conditions treated with radiotherapy and chemotherapy, an increasing number of survivors are facing the absence of ovarian function. Irradiation is known to induce POF and was once a method of castration. The reproductive system is one of the major sites of secondary effects of anticancer treatment (Ogilvy-Stuart and Shalet 1993). Different therapeutic insults will be associated with different risks for early menopause. It is important to have accurate information on the gonadotoxicity of different cancer treatment regimens to improve patient information and optimize approaches for fertility preservation. For survivors of treatment for cancer, treatment with radiotherapy below the diaphragm and alkylating agent chemotherapy, the average age at menopause was approximately 31 years. Other modes of treatment conferred an excess risk of ovarian failure, although not as great (Byrne 1999; Figure 16.5).

Anderson and Cameron (2007) detected changes in the ultrasound markers of the ovarian reserve (OR), with decreases in both ovarian volume and antral follicle count during chemotherapy. Anderson and Cameron (2007) assessed the OR markers in premenopausal women to investigate and compare the effects of chemotherapy and long-term gonadotrophin withdrawal on ovarian function, and detected changes in ultrasound markers of the OR, with decreases in both ovarian volume and antral follicle count during chemotherapy. These data confirm the value of AMH

concentration as an early indicator of ovarian ageing, including assessment of chemotherapy-induced ovarian follicle loss. FSH and AMH concentration measurements may be useful for the comparison of ovarian toxicity of different chemotherapy regimens. Adverse effects on female reproductive function may be mediated through effects at one or more levels of the HPO axis (Wallace et al 1989) or at the uterus (Critchley et al 1992). Commonly, anticancer treatment (chemotherapy, particularly alkylating agents, and scatter radiation to the ovary) affects the ovary as a consequence of depletion of the stock of primordial follicles, thereby advancing or inducing menopause (Critchley and Wallace 2005). Effects on the hypothalamus and pituitary may be subtle. High-dose cranial irradiation is known to have direct damaging effects, but the effects of the lower doses used in the management of childhood leukaemia are, as yet, uncertain. Data concerning ovarian function after treatment of standard risk leukaemia have been reassuring (Wallace et al 1993). A recent study by Bath et al (2001) examined HPO function in 12 women in first remission from childhood acute lymphoblastic leukaemia. This study revealed a high prevalence of short luteal phases (<11 days) among these women compared with a normal control group. A reduced LH excretion (probably secondary to cranial irradiation) and ovarian oestrogen production (probably reflecting a reduction in gonadotrophic stimulus) were observed in the women with acute lymphoblastic leukaemia. Such disturbances in LH secretion may have an effect on reproductive potential (Box 16.7).

Ovarian reserve

The OR, a term that has evolved in the era of assisted reproductive technology, refers to the residual oocyte-granulosa cell repertoire. An improved ascertainment of OR status may help to optimize the planned therapeutic intervention, and

Box 16.7 Genetic abnormalities related to premature ovarian failure

- X monosomy (Turner's syndrome)
- X deletions/translocations
- Autosomal abnormalities

thus minimize the emotional and financial strain placed upon couples seeking fertility treatment. A spectrum of markers prognostic of the OR are validated to varying degrees in the infertile population. These include biochemical markers (FSH, prostaglandin E₂, inhibin B, AMH and FSH:LH ratio) and ovarian morphometric markers (ovarian volume, antral follicle count and mean ovarian diameter) assessed in the early follicular phase (basal) of the menstrual cycle (Bowen et al 2007).

Raised follicle-stimulating hormone (FSH) is important as it is the first measurable parameter that changes in reproductive ageing. Pituitary FSH production is co-regulated by inhibin and oestradiol, acting via negative endocrine feedback (Muttukrishna et al 2000). Anti-Müllerian hormone (AMH) has recently been suggested as a more accurate indicator of the presence of ovarian follicles (Durlinger et al 2002). Since there is no change in AMH levels in response to gonadotrophins, AMH can be measured throughout the cycle in contrast to the other parameters, which can only be determined during the early follicular phase: an advantage for both patients and clinicians. It reflects earlier stages of follicle development than inhibin B and oestradiol, and thus is believed to more closely approximate the number of primordial follicles in the ovary. Inhibin B is a product of the granulosa cells. It has recently been shown that the value of inhibin B as a measure of the OR is greatly increased following administration of a single dose of FSH to stimulate granulosa cell function in small healthy follicles.

A nationwide prospective cohort study in the Netherlands concluded that, compared with inhibin B and antral follicle count, AMH was more consistently correlated with the clinical degree of follicle pool depletion in young women presenting with elevated FSH levels (Knauff et al 2009). AMH may provide a more accurate assessment of the follicle pool in young hypergonadotropic patients, especially in the clinically challenging subgroups of patients with elevated FSH and regular menses (i.e. incipient ovarian failure), and in hypergonadotropic women with cycle disturbances not fulfilling the diagnostic criteria for POF (i.e. transitional ovarian failure). Ultrasound measurement of both ovarian volume and antral follicle count (the number of small follicles present) is also of value.

Assessment of the OR by measuring the ellipsoid ovarian volume via transvaginal ultrasound is cumbersome and time consuming as it requires an additional third-dimensional measurement, not routinely taken in clinical practice.

Whilst all individual ovarian parameters (width, length or an average of the two) reliably reflect the OR in premenopausal infertile women, the mean ovarian width (as determined by ultrasound) exhibits a more robust relationship with OR status compared with ovarian length or the average of the two dimensions (Fratarelli et al 2002).

Endocrine disorders arising outside the HPO axis leading to chronic anovulation

Other endocrine disorders may interfere with the normal feedback loops of the HPO axis, thereby causing a disturbance in cyclical ovarian activity and manifesting as amenorrhoea or oligomenorrhoea (Baird 1997). Thyroid disease may cause amenorrhoea and oligomenorrhoea. There is an increase in circulating concentrations of oestrogen and testosterone in hyperthyroidism as levels of sex-hormone-binding globulin increase. In hypothyroidism, there may be associated raised levels of prolactin due to stimulation with thyrotrophic-releasing hormone. In adrenal disease, the excessive secretion of sex steroids leads to amenorrhoea, as gonadotrophin secretion will be suppressed.

Diagnosis and Management of Oligomenorrhoea and Amenorrhoea

The successful management of oligomenorrhoea and amenorrhoea is dependent upon the correct diagnosis and an assessment of the requirements of the patient. Patients will articulate different needs which may include advice about future fertility prospects, fertility control, symptoms of hirsutism, delayed secondary sexual development, protection from osteoporosis and endometrial protection from unopposed oestrogen action. A thorough history and clinical examination (as appropriate) are of paramount importance in establishing the diagnosis of an endocrine disorder, complemented with an appropriate examination and conduct of straightforward endocrine investigations. Since the withdrawal of sex steroids results in endometrial bleeding, a detailed menstrual history will be extremely valuable in the determination of endogenous ovarian activity. Provided that the patient has not been administered exogenous hormone preparations, a report of only light menstrual bleeding will indicate sufficient ovarian production of oestrogen to produce endometrial proliferation. Hence if a history is given of oligomenorrhoea, there must be some capacity for ovarian activity. It is essential to exclude an anatomical cause of amenorrhoea. The bimanual assessment of a young woman who has never been sexually active is inappropriate. The examination of secondary sexual characteristics (breast development) and the external genitalia of an adolescent should be performed in the presence of the patient's parent. Indeed, a deferred examination separate from the initial consultation may be most appropriate, thereby providing an opportunity for confidence to be established in the subsequent doctor-patient relationship. Modern imaging techniques, particularly transabdominal ultrasound, are valuable non-invasive modes of establishing information about reproductive anatomy. In the context of a history of amenorrhoea, an enquiry about experience of hot flushes may elicit a diagnosis of ovarian failure. A detailed drug history (see Box 16.6) and information about diet, exercise habit and weight change are essential. Furthermore, enquiry about life events producing psychological stress should be made. Signs of hyperandrogenism may be evident, such as hirsutism, acne and balding. Enquiry about the presence of galactorrhoea should be made. A distinction is required between hyperandrogenism and virilization, and acanthosis

nigricans is a feature of severe insulin resistance. An assessment of the development of secondary sexual characteristics and BMI is important. Baseline endocrine investigations should include the exclusion of pregnancy (most common cause of secondary amenorrhoea), measurement of serum gonadotrophin (FSH and LH), oestradiol and prolactin concentrations, and markers of thyroid function (thyroxine and/or thyroid-stimulating hormone) if there are clinical signs of thyroid disease or any signs of hyperprolactinaemia. It is also possible to assess endogenous ovarian activity over the cycle with once- or twice-weekly serial measurements of oestradiol and progesterone concentrations in serum (or plasma) or their metabolites in urine. Serum androgens (testosterone) should be measured in subjects with hirsutism or androgenization. The possible use of transabdominal (and, where appropriate, transvaginal) ultrasound as mentioned above may be a useful adjunct to clinical examination. These baseline endocrine investigations will permit the categorization of patients into essentially one of four diagnostic groups: hypergonadotrophic hypogonadism, hyperprolactinaemia, hypogonadotrophic hypogonadism and normogonadotrophic anovulation (Baird 1997; Figure 16.6).

Ovarian failure

The endocrine status in ovarian failure (or, rarely, resistant ovary syndrome) is identified by the demonstration of a raised serum FSH concentration (>30 IU/l) and a low serum oestradiol level (<60 pmol/l). In cases of primary amenorrhoea and thus primary ovarian failure, a chromosomal analysis will permit the identification of women with testicular dysgenesis. It is important that women have their residual gonadal tissue removed on account of the risk of neoplastic change. Sex steroid replacement therapy with cyclic oestrogen and progestogen should be started without delay, particularly in girls with primary ovarian failure, in the latter group to induce secondary sexual characteristics and among all affected patients in order to prevent premature bone loss. This should be continued until the age of 50–54 years.

Hyperprolactinaemia

Although the true prevalence of hyperprolactinemia is difficult to establish, it is estimated that among women presenting with reproductive disorders, approximately 15% with anovulation and 43% with anovulation and galactorrhea have hyperprolactinemia. Hyperprolactinaemia (raised serum prolactin) is diagnosed when concentrations of prolactin are outwith the normal range (up to 500 mU/l). It should be noted that serum prolactin levels may be transiently and moderately raised (>700 mU/l) at times of stress. A persistent, albeit moderate, elevation of prolactin will be recorded in the presence of hypothyroidism, and is a common feature among women with PCOS. In the latter group, levels as high as 2500 mU/l have been reported (Baird 1997, Balen 2000). Thyroid disease may be excluded with estimation of serum thyrotrophin concentrations. Patients with PCOS-related hyperprolactinaemia may be distinguished from women with unrelated hyperprolactinaemia and polycystic ovaries on ultrasound by means of a progestogen challenge test (Lunenfeld and Insler 1974),

which will induce a withdrawal bleed from an oestrogen-primed endometrium. Serum prolactin measurements >1500 mU/l will require more detailed investigations. Imaging of the pituitary fossa is best undertaken with either magnetic resonance imaging or computed tomography. Serum prolactin concentrations >5000 mU/l are associated with macroprolactinomas (>1 cm diameter). Diagnostic imaging will detect the presence of a hypothalamic tumour or a non-functioning pituitary tumour causing compression of the hypothalamus or a pituitary microadenoma (Figures 16.7 and 16.8).

Hypogonadotrophic hypogonadism

Hypogonadotrophic hypogonadism is characterized by reduced FSH and LH secretion, and consequent absence of follicular development and oestradiol production. Before puberty, the situation will manifest as primary amenorrhoea and lack of development of secondary sexual characteristics. Usually, however, no organic disease is identified in the hypothalamus or anterior pituitary gland. On rare occasions, it may be necessary to distinguish hypothalamic causes from pituitary causes with a GnRH stimulation test (100 µg s.c.) following 1 week of ethinyl oestradiol orally at a dose of 5–10 µg/day. The administration of this supraphysiological dose of GnRH assesses the responsiveness and capacity of the pituitary to secrete gonadotrophins (Yen et al 1973). A better index of 'pituitary reserve' is

Figure 16.7 Magnetic resonance image of a pituitary microadenoma (coronal T1 non-contrast image) demonstrating a focal rounded area of low signal in the left half of the gland measuring 7 mm. The lesion distorts both the superior and inferior margins of the pituitary gland. The pituitary infundibulum is midline with no evidence of extension into the suprasellar cistern.

provided by assessment of the response to repeated physiological doses of GnRH (5–10 µg) at 2–3-h intervals (rather than a single supraphysiological injection). This assessment of pituitary secretory capacity correlates better with the degree of spontaneous secretion, as indicated by the amplitude and frequency of LH pulses. Raised FSH and LH concentrations in response to GnRH stimulation may indicate hypothalamic failure. Such patients require imaging to exclude a craniopharyngioma and consideration of Kallman's syndrome.

Normogonadotrophic anovulation

Normogonadotrophic anovulation occurs in one-third of women with secondary amenorrhoea who display normal gonadotrophin concentrations. Women with PCOS should be considered in this category, and their diagnosis and treatment are discussed in depth in Chapter 18.

Therapeutic Issues

Oestrogen deficiency

In addition to a thorough explanation to patients about the diagnosis and its consequences, women with ovarian failure require sex steroid replacement therapy with cyclic oestrogen and progestogen. Lack of oestrogen after the normal age of menopause has an adverse effect on bone and blood vessel health. Premenopausal levels of oestradiol in women with normal ovarian function protect the female

skeleton from demineralization (Howell and Shalet 1999). The cardiovascular protective effects of oestrogen are well documented in older women who have had endogenous protection for many years before the menopause (Mendelsohn and Karas 1999). In Turner's syndrome, there is evidence to suggest that women do not achieve peak bone mass and have a higher rate of fractures (Davies et al 1995). In girls with Turner's syndrome, the rate of bone mineral acquisition on the oral contraceptive pill is less than is seen in normal adolescents, with a 25% reduction in bone mineral content from that predicted for age, height, weight and bone size. It is possible that this may be a reflection of suboptimal oestrogen replacement. Research to date has delivered well-evaluated hormone replacement regimens for older women designed to mitigate the adverse effects of lack of oestrogen and taken for somewhere in the order of 10 years. Some women seek alternatives to conventional hormone replacement therapy (HRT) which can include antidepressants (e.g. serotonin) and herbal preparations. A recent systematic review looking at black cohosh as a treatment for menopausal symptoms concluded that the efficacy was uncertain and that further trials are warranted (Borrelli and Ernst 2008). Currently, younger women with a premature menopause are offered combined sex steroid replacement in the convenient form of the combined oral contraceptive pill or HRT, which should be continued at least until the average age of natural menopause (52 years in the UK). This view is endorsed by regulatory bodies such as the Committee on Safety of Medicines (now the Commission on Human Medicines) in the UK (Pitkin et al 2007). These preparations are not designed to achieve physiological replacement of oestrogen or progesterone, either in dosage or biochemical structure. The optimal mode and formulation of sex steroid replacement have not yet been established for young women with ovarian failure. The well-documented risks with HRT relate to the postmenopausal age category and not those with premature menopause. Indeed, recent guidelines from the British Menopause Society (2008) confirm that there is no increase in the risk of breast cancer or cardiovascular disease with the use of HRT for patients with premature menopause. There may also be a need for topical oestrogen in the form of vaginal cream or pessary. In addition, testosterone replacement may need to be considered where there are marked symptoms of reduced libido; this is delivered in a patch. Patients should be warned about possible side-effects of excess hair growth and acne. A recent randomized, double-blind, placebo-controlled trial showed transdermal testosterone therapy to be very effective (Shifren et al 2006). Early menopause is a risk factor for osteoporosis, so women with an early menopause should have bone density testing performed within 10 years of menopause so that osteopenia or osteoporosis will be diagnosed early and appropriate antiresorptive therapy initiated.

Management of hyperprolactinaemia

The management of women with hyperprolactinaemia has to take into account the individual's desire or otherwise for pregnancy, her oestrogen status, and the presence/absence and size of a pituitary tumour. Women who describe regular menses and who are found to have raised prolactin

concentrations do not require treatment unless their menstrual cycles are anovulatory and they wish for pregnancy (Soule and Jacobs 1995). Dopaminergic agents are recommended as the primary therapy for prolactin-secreting adenomas and idiopathic hyperprolactinaemia (Webster et al 1994). The effects induced by dopamine agonists are suppressive but not tumoricidal. Thus, the therapeutic effect is only maintained for as long as the drug is administered. Consequently, in most cases, treatment has to be continued life-long with a few exceptions, in whom normoprolactinaemia persists even after discontinuation of dopamine agonists. Surgery (trans-sphenoidal adenectomy) is usually reserved for dopamine-resistant conditions, intolerable side-effects of therapy and where there is failure to adequately shrink a macroadenoma (Balen 2000). Dopamine agonists include bromocriptine and cabergoline, the latter being better tolerated than the former, which may be explained in part by the longer half-life which results in fewer changes in drug concentration in the blood. There have been recent guidelines from the European Medicines Agency (2008) regarding the use of dopamine agonists and the risk of cardiac fibrosis. Prescribing recommendations include avoiding using such drugs in any patient with a history of cardiac fibrosis, monitoring for signs of fibrosis throughout treatment by blood tests or chest X-rays, and ensuring adherence to a daily maximum dose of 30 mg bromocriptine. The fall in circulating prolactin concentrations with therapy is accompanied by an increase in frequency of LH pulses. The return of menstruation is usually associated with anovulatory cycles. Since normal ovarian cycles have usually returned by 6 months, it may be necessary to provide contraception unless immediate fertility is desired. A tumour >1 cm in diameter should be surgically removed or reduced in size by dopaminergic therapy prior to pregnancy, since there is a small risk of tumour enlargement during pregnancy. Once pregnancy is diagnosed, dopaminergic therapy should be discontinued. There is no evidence to indicate that bromocriptine is teratogenic. Bromocriptine therapy should be recommenced if there was evidence of tumour enlargement during the pregnancy. Should hyperprolactinaemia be a consequence of drug administration itself (see Box 16.6), cessation of the offending preparation should be recommended after due consultation with other health professionals involved in the patient's care. If continuation of a psychotropic preparation is essential for the patient's good health (e.g. in the case of schizophrenia), administration of a low-dose oral contraceptive preparation, in addition to continuation of the required dopaminergic therapy, will provide protection against coincident symptoms of oestrogen deficiency. Serum concentrations of prolactin should continue to be monitored. Surgical intervention is necessary for non-functioning tumours. These tumours are detected by a combination of imaging and a serum prolactin concentration <3000 milliunits/l (Balen 2000). A suprasellar extension of the tumour will also be an indication for surgery when dopaminergic therapy has failed to produce regression, or there is a wish for pregnancy. Surgery may carry a risk of hypopituitarism and, if present, usually manifests promptly following surgery. Pituitary irradiation (although not common) has a risk of incipient hypopituitarism and therefore necessitates long-term surveillance (Soule and Jacobs 1995).

Fertility Issues

There may be reasonable optimism about future fertility prospects for women with amenorrhoea, provided that they do not have POE. Women with oligomenorrhoea, however, have a slightly reduced chance overall (Hull et al 1982). In women with normal gonadotrophin concentrations, it is relatively easy to restore fertility with induction of ovulation with an antioestrogen preparation such as clomiphene citrate. Some women will also require administration of human chorionic gonadotrophin to induce ovulation, despite a response to clomiphene in terms of follicular development. Patients with low gonadotrophin concentrations will require ovulation induction with gonadotrophins or pulsatile GnRH therapy. Detail about ovulation induction regimes is addressed in Chapter 17. The assessment of oestrogen status is a useful index of likely responsiveness to ovulation induction agents, such as clomiphene citrate. Furthermore, it identifies the requirement for long-term hormone replacement, where there is a risk of osteoporosis due to oestrogen deficiency, or for endometrial protection with a progestogen, where there is continuous unopposed oestrogen stimulation. The progestogen challenge test utilizes the endometrial response to administration and withdrawal of progestogen. The oestrogen-primed endometrium will exhibit a withdrawal bleed some 24–48 h following cessation of progestogen administration. An alternative mode of assessment of oestrogen status is the measurement of endometrial thickness with ultrasound. The restoration of fertility may be possible in young women with ovarian failure with HRT and assisted reproduction which includes the use of donor oocytes and embryo transfer. More controversial is the use of assisted reproductive technology and surrogacy for the fulfilment of family desires among women who have congenital absence of the uterus or who have undergone hysterectomy for cancer at a young age (Brinsden et al 2000).

Contraceptive Advice

It is inevitable that young women with oligomenorrhoea or amenorrhoea will have concerns about contraceptive requirements and perceived influences on future fertility potential. Furthermore, contraception may be required after ovulation induction therapy. The usual range of contraceptive options should be considered. Copper intrauterine contraceptive devices (IUCD) are often avoided in nulliparous patients. Women with oligomenorrhoea or amenorrhoea are likely to have a degree of oestrogen deficiency with a small uterus. In these women, even those who are parous, insertion and containment of the IUCD may be problematic. There is no evidence that combined oestrogen/progestogen contraceptive preparations contribute to subsequent amenorrhoea or subfertility. Indeed, there are positive benefits for the use of such preparations. Protection against unopposed oestrogen stimulation of the endometrium in women with chronic anovulation is provided by use of the combined pill or administration of cyclic progestogens.

KEY POINTS

1. Physiologically regular menses are an indication of cyclical ovarian activity, in turn dependent upon an intact HPO axis. Amenorrhoea and oligomenorrhoea are symptoms of ovarian and reproductive dysfunction.
2. Amenorrhoea is physiological at certain critical times in a woman's life, these being prepuberty, during pregnancy and lactation, and in the postmenopausal period. Pathological amenorrhoea may be primary or secondary, and there may be common aetiology.
3. The hypothalamic–pituitary axis is regulated at two levels. At a higher level, GnRH neurones within the hypothalamus are stimulated by afferent inputs from the central nervous system. At a lower level, the output of FSH and LH from the anterior pituitary reflects GnRH activity. Gonadotrophin synthesis, in turn, is influenced by endocrine feedback from the ovaries as well as paracrine mechanisms and other extrinsic factors. Disturbances in menstrual pattern will be the consequence of either a structural or a functional defect in the tightly controlled feedback system involving the hypothalamus, pituitary and ovary.
4. Baseline endocrine investigations will permit the categorization of patients into essentially one of four diagnostic groups: hypergonadotrophic hypogonadism, hyperprolactinaemia, hypogonadotrophic hypogonadism and normogonadotrophic anovulation.
5. The number of follicles in the human ovary declines steadily from midlife onwards. POF is the triad of amenorrhoea and elevated FSH and LH in women less than 40 years of age (hypergonadotrophic hypogonadism). Subjects with gonadal failure are oestrogen deficient. One of the most common chromosomal causes of primary ovarian failure (and primary amenorrhoea) is Turner's syndrome. Women with ovarian failure require sex steroid replacement therapy with cyclic oestrogen and progestogen. Oestrogen deficiency has an adverse effect on bone (osteoporosis) and blood vessel health. OR can be measured (or at least estimated) by measuring FSH, prostaglandin E2, inhibin B, AMH, FSH:LH ratio and ovarian morphometric markers (ovarian volume, antral follicle count and mean ovarian diameter).
6. Hyperprolactinaemia is diagnosed when prolactin concentrations are outwith the normal range. Serum levels may be transiently raised at times of stress. Serum prolactin measurements >1500 milliunits/l require diagnostic imaging of the pituitary fossa. Approximately 15–20% of women with secondary amenorrhoea display elevated serum prolactin concentrations. In 1–2% of cases, the hyperprolactinaemia is induced by drugs that inhibit dopamine action or production. Only half of women who present with hyperprolactinaemia describe galactorrhoea. It is most important to consider the prolactin concentration in the context of the associated ovulatory disorder. Significant hyperprolactinaemia is usually associated with oligomenorrhoea or amenorrhoea.
7. Hypothalamic hypogonadism is characterized by reduced FSH and LH secretion, and an absence of follicular development and oestradiol production. As a rule, no organic disease is identified in the hypothalamus or anterior pituitary gland.
8. Severe weight loss, stress and excessive exercise habit are all associated with cessation of hypothalamic function. In each of these situations, there is a decrease in GnRH neuronal activity in the hypothalamus with a consequent decrease in gonadotrophin secretion. Thus, ovarian follicular development and ovulation fail to occur and a hypo-oestrogenic state develops. A chronic hypo-oestrogenic state will carry significant risk of premature osteoporosis and cardiovascular disease.
9. Other endocrine disorders, such as thyroid and adrenal disease, may interfere with the normal feedback loops of the HPO axis, cause disturbance of cyclical ovarian activity and thus lead to oligomenorrhoea or amenorrhoea.
10. Successful management of amenorrhoea and oligomenorrhoea is dependent upon the correct diagnosis and assessment of the needs of the patient. Each woman will have different requirements, which may include advice on future fertility prospects, fertility control, symptoms of hirsutism, delayed secondary sexual development, risk of osteoporosis and endometrial protection from unopposed oestrogen action.
11. There may be reasonable optimism about future fertility prospects for women with amenorrhoea, provided that they do not have POF. Women with oligomenorrhoea have a slightly reduced chance overall. The mainstay of management is ovulation induction. The restoration of fertility is possible in young women with POF with hormone replacement and assisted reproductive technology that includes the use of donor oocytes and embryo transfer.

Acknowledgements

The material in this chapter contains contributions from previous editions and the authors are grateful to previous authors for the work done. The authors wish to thank Dr

Colin Duncan, University of Edinburgh, for helpful comments on the manuscript content and Mrs Sheila Milne for secretarial assistance.

Introduction

The aim of ovulation induction is to achieve development of a single follicle and subsequent ovulation in anovulatory infertile women. The ability to induce ovulation is possible in most women, with excellent conception rates. Anovulation accounts for 20–25% of the causes of infertility, and clinicians who manage infertile couples ought to have a sound understanding of the control of follicular development in a normal cycle (see Chapter 15), causes of anovulation (see Chapter 16), appropriate investigations and different treatment options, including their indications and risks. This chapter will briefly review the physiology of ovulation, including the basic principles of ovulation induction, and describe treatment strategies based on the underlying cause of the anovulation.

Principles of Ovulation

The ovary has two main functions: the cyclic release of haploid oocytes for fertilization by spermatozoa, and the production of steroid hormones (mainly oestrogen and progesterone). Both activities occur from puberty, when full sexual maturation has taken place, until the menopause, controlled by a sequence of hypothalamic–pituitary–ovarian interactions which, in turn, are synchronized by the endocrine, paracrine and autocrine secretory products of the ovary.

Follicular development: recruitment, selection and dominance

The primordial follicle constitutes the fundamental functional unit of the ovary. The primordial follicles contain oocytes that enter meiosis and are arrested in the diplotene stage of meiotic prophase to become primary oocytes. They can stay in this arrested phase for up to 50 years. Regular recruitment of primordial follicles occurs from puberty. The following stages of follicular development have been identified en route to ovulation: first, the primordial follicle becomes a primary or preantral follicle, then a secondary or antral follicle and finally a preovulatory follicle. The duration of each stage varies, with the primary to preantral stage being the longest and the preovulatory stage being the shortest.

In humans, approximately 15–20 early antral follicles are recruited for development at the start of each menstrual cycle. Of these 15–20 follicles, one usually emerges as dominant and is competent to ovulate. It takes approximately 85 days for a primordial follicle to reach the preovulatory stage. This follicular growth and development is regulated by gonadotrophins, and it is acknowledged that a lack of gonadotrophins leads to apoptotic death of the oocyte with subsequent accumulation of leukocytes and macrophages, as well as formation of fibrous scar tissue. This process is called 'atresia'.

The follicle destined to ovulate is recruited from these preantral follicles in the first days of the menstrual cycle. An

increase in follicle-stimulating hormone (FSH) is the critical feature in rescuing a cohort of follicles from atresia, eventually allowing a dominant follicle to emerge and proceed to ovulation. Maintenance of this increase in FSH for a critical duration of time over 4–6 days is essential.

The first signs of follicular development consist of an increase in the size of the oocyte and a change in the shape of the granulosa cells as they become more cuboidal. Small gap junctions also appear between the oocyte and the granulosa cells. The stromal cells differentiate into two layers: the theca interna and the theca externa. The granulosa layer is separated from the stromal cells by a basement membrane called the 'basal lamina'.

As the oocyte enlarges, it enters the preantral stage. During this phase, there is further granulosa cell proliferation and growth. This is initiated by FSH. FSH also induces steroidogenesis in the granulosa cells and, in particular, oestrogen production. The oocyte is surrounded by a membrane called the 'zona pellucida'. Under the synergistic effect of oestrogen and FSH, there is an increase in the production of follicular fluid. This leads to the formation of a cavity, called the 'antrum', and the follicle is now described as the antral follicle. The granulosa cells form the cumulus oophorus.

Only the cells of the theca interna possess receptors for luteinizing hormone (LH), whereas the granulosa cells bind FSH. Under the influence of gonadotrophins, the antral follicles produce steroids. The main oestrogens produced are oestradiol-17 β and oestrone. In addition to this, antral follicles produce 30–70% of the circulating androgens, mainly androstenedione and testosterone. In particular, it is the thecal cells that produce androgens from acetate and cholesterol, and this action is stimulated by LH. On the other hand, the granulosa cells cannot produce androgens, but aromatize them to oestrogens; this process of aromatization is stimulated by FSH.

Follicular growth starts with the regression of the corpus luteum at the end of the previous cycle. As the levels of steroid hormones and inhibin drop, their inhibitory effect on FSH is abolished and FSH levels rise. This increase starts approximately 2 days prior to menstruation. As the follicles grow, the production of oestradiol and inhibin increases and FSH levels subsequently fall. The dominant follicle will be selected from day 5–7 of the menstrual cycle. The selection of a single dominant follicle appears to be the result of two oestrogen actions: a positive influence of oestrogen on FSH action within the maturing follicle, and a negative feedback mechanism on FSH at the hypothalamic–pituitary level. This latter action leads to a decline in gonadotrophin levels and ultimately to atresia of the less-developed follicles. Local paracrine–autocrine factors are also involved in this process, such as tumour necrosis factor and anti-Müllerian hormone. The dominant follicle is not affected by this decline in FSH levels, as it is more sensitive to FSH. Provided that a critical exposure of FSH was initially sustained, the dominant follicle continues to grow. In turn, FSH induces the development of LH receptors on the granulosa cells. Thus, LH plays a crucial role in the late stages of follicular development (Figure 17.1).

As the dominant follicle grows, it produces oestradiol. This explains the significant rise in oestradiol levels observed in the late follicular phase. High levels of oestradiol exert a positive feedback effect on LH secretion and enhance the

follicle's sensitivity to FSH. LH enhances androgen production in the theca cells, which leads to further oestrogen secretion by the granulosa cells via the process of aromatization. At midcycle, oestradiol levels reach a peak; this induces the LH surge, resumption of meiosis in the oocyte, luteinization of the granulosa cells and synthesis of prostaglandins. The prostaglandins stimulate the release of proteolytic enzymes within the follicular wall, which lead to ovulation (release of oocyte) 34–36 h after the LH surge commences.

Ovulation Disorders

Assessing ovulation

The choice of treatment to induce ovulation depends on reaching the correct diagnosis of the cause of anovulation. A thorough medical history and physical examination are the preliminary steps, and further investigations should be undertaken as indicated. It is highly recommended that these investigations should be conducted in a specialist centre, where there is access to skilled ultrasonography, radiology and a specialist endocrine laboratory. These tests will help the clinician to diagnose the cause of anovulation and exclude any important underlying pathology. Thyroid disease, hyperprolactinaemia, pituitary and ovarian tumours, polycystic ovary syndrome (PCOS), adrenal disease, extremes of weight and eating disorders are all associated with ovulation dysfunction. Early diagnosis is essential, as treatment of the underlying cause is more likely to succeed and prevent any long-term health consequences.

Classification

Ovulation disorders can be classified according to the anatomical site where the hypothalamic–pituitary–ovarian axis

Figure 17.1 Follicle-stimulating hormone (FSH) threshold and window.

is deficient. The World Health Organization (WHO) classifies ovulation disorders into three groups, as follows.

- Group I: hypothalamic–pituitary failure. This group includes women with hypothalamic amenorrhoea or hypogonadotrophic hypogonadism. This includes anovulation related to stress, exercise, weight loss, anorexia nervosa, Kallmann's syndrome and isolated (idiopathic) gonadotrophin deficiency. It does not include women with hypothalamic or pituitary tumours. This group of women have low serum FSH, LH and oestrogen levels, but normal prolactin.
- Group II: hypothalamic–pituitary dysfunction. This group includes women with amenorrhoea or oligomenorrhoea, with or without hyperandrogenism. This group predominantly comprises women with PCOS. Characteristically, these women exhibit normal FSH, oestrogen and prolactin levels, and variable changes in serum LH and testosterone.
- Group III: ovarian failure. This category includes women with amenorrhoea and elevated serum FSH and LH.
- Hyperprolactinaemic anovulation is considered a separate entity.

History

The majority of women of reproductive age have regular cycles ranging from 25 to 35 days. Usually, the presence of such cycles indicates ovulation.

Nevertheless, irregular, erratic or infrequent menses are suggestive of anovulation. Therefore, a detailed menstrual history should be taken. Amenorrhoea (absence of menstruation for 6 months), oligomenorrhoea (menses occurring less frequently than 6 weeks) and polymenorrhoea (menses occurring more frequently than 21 days) are associated with anovulation.

In addition, galactorrhoea, hot flushes and symptoms suggestive of thyroid disease could indicate an underlying ovulation dysfunction.

A careful gynaecological, medical, surgical and family history should be elicited. In particular, other causes of infertility should be excluded. A previous history of pelvic inflammatory disease, use of an intrauterine device, previous ectopic pregnancy or previous pelvic surgery is suggestive of tubal/ovarian pathology. In addition to this, any previous fertility investigations and therapies should be noted, and the absence of a contributory male factor should be confirmed.

Physical examination

The height and weight of the woman are of particular importance. Any deviation from normal should be noted, as this could be directly related to the underlying cause of anovulation (e.g. obesity and PCOS, short stature and Turner's syndrome etc.). A more sensitive indicator is the body mass index (BMI), which is calculated from weight in kg/height in m². The range for BMI is as follows.

- Underweight: <18.5
- Normal: 18.5–24.9

- Overweight: 25.0–29.9
- Obesity: 30.0–39.9
- Extreme obesity: ≥40

A general physical examination should be performed. This will include examination of the thyroid gland, breasts, facial and body hair. A thorough gynaecological examination must also be undertaken.

Investigations

Assessing ovulation is one of the primary investigations of infertility. Nevertheless, other factors should be evaluated. As 30–40% of cases of infertility are due to a male factor, a semen analysis should be requested early in the course of the investigations. Moreover, the female partner should have a test to assess tubal patency, such as a hysterosalpingogram, a diagnostic laparoscopy and dye test, or a hystero-ultrasonography (hycosy).

A serum progesterone measurement is the simplest and most reliable test to evaluate ovulatory function. The measurement of serum progesterone level should be performed in the midluteal phase (i.e. 7 days before the expected onset of the next period). Typically, in a 28-day cycle, the test is conducted on the 21st day of the menstrual cycle. Nevertheless, in women with prolonged, irregular cycles, serum progesterone is measured later in the cycle (i.e. on day 28 of a 35-day cycle) and is repeated weekly thereafter until the next menstruation. A mistimed blood sample is the most common cause of an abnormal result; thus, the first day of the next menstrual cycle should be recorded, and the midluteal phase will be calculated based on that to evaluate whether the test was appropriately timed.

Serum progesterone levels above 30 nmol/l are suggestive of ovulation. Any abnormal result indicates the need for further hormonal investigations. These will include measurement of serum FSH, LH and prolactin and thyroid function tests. Serum FSH and LH should be performed on day 2–5 of the cycle to avoid confusion with the normal, mid-cycle surge. In amenorrhoeic women or women with very infrequent cycles, the measurement of gonadotrophins can be done at any time and their interpretation will be based on the timing of their next menstruation. Both prolactin and thyroid function tests can be done at any time during the cycle.

The normal reference value for prolactin may vary between different laboratories. Usually, levels above 600 mIU/ml are considered abnormal. Raised prolactin concentrations should be confirmed by a repeat measurement. The evaluation of hyperprolactinaemia should include pituitary/hypothalamic imaging, such as radiography, computed tomography or magnetic resonance imaging. The pituitary imaging is essential to exclude a prolactin-producing adenoma or an empty sella. Moreover, as primary hypothyroidism can lead to secondary hyperprolactinaemia, thyroid function tests are indicated in the presence of hyperprolactinaemia and a careful drug history to exclude a pharmacological cause.

In the presence of low gonadotrophin levels, pituitary/hypothalamic imaging is indicated in order to exclude a space-occupying lesion, as well as a full pituitary hormone secretion assessment.

In the case of PCOS, the hormonal investigations should include serum androgens (testosterone, free testosterone, androstenedione and dehydroepiandrosterone sulphate), as they are often elevated, and baseline 17OH-progesterone. Depending on the results, adrenocorticotrophic hormone concentrations may be measured to exclude adrenal pathology. If PCOS is suspected, a transvaginal ultrasound should be performed to assess the ovaries and look for the characteristic peripheral follicles ('necklace sign'). The criteria used for the ultrasonographic diagnosis of PCOS include the presence of more than 10 follicles with a diameter of 2–10 mm and increased density of the ovarian stroma (Adams et al 1986).

If premature ovarian failure is diagnosed, further investigations should include chromosome analysis and autoantibody screening.

Basal body temperature (BBT) charts have also been used for assessing ovulation, as ovulatory cycles have been associated with a classic biphasic BBT pattern. The woman is asked to record her temperature every morning, before getting out of bed. Usually, the temperature shows a rise after ovulation. Chaotic BBT recordings are suggestive of anovulation. Nevertheless, the BBT may not appear clearly biphasic in some patients with ovulatory cycles. Therefore, BBT charts are not considered reliable to predict ovulation, and their use is not recommended alone without serum progesterone measurements.

Diagnosis and Treatment

Based on the results of the above investigations, the causes of anovulation can be divided into four main categories (see Box 17.1).

Box 17.1 Classification of ovulation disorders

Intrinsic ovarian failure

- Genetic
- Autoimmune
- Others (e.g. chemotherapy and radiotherapy)

Secondary ovarian dysfunction

Disorders of gonadotrophin regulation

Specific

- Hyperprolactinaemia
- Kallmann's syndrome (WHO Group I)

Functional (WHO Group II)

- Weight loss
- Exercise
- Drugs
- Idiopathic

Gonadotrophin deficiency (WHO Group I)

- Pituitary tumour
- Pituitary necrosis or thrombosis

Disorders of gonadotrophin action (WHO Group II)

- Polycystic ovary syndrome

Hyperprolactinaemia

Causes of hyperprolactinaemia include:

- prolactin-producing adenomas (microadenomas <1 cm, macroadenomas >1 cm);
- any masses that apply pressure on the pituitary stalk and therefore block the inhibitory effect of the hypothalamus;
- primary hypothyroidism;
- drugs that inhibit central dopaminergic activity, such as oestrogen (combined oral contraceptive), dopamine receptor antagonists (metoclopramide, phenothiazines), opioids and dopamine-depleting agents (reserpine, methyl dopa);
- chronic renal failure; and
- ectopic prolactin secretion by an extrapituitary tumour.

High levels of prolactin interfere with the pulsatile secretion of gonadotrophin-releasing hormone (GnRH) and subsequently impair normal ovarian function. Therefore, women with hyperprolactinaemia may present with menstrual irregularities, anovulation and galactorrhoea.

In the case of microprolactinomas, the mainstay of therapy is the administration of dopamine agonists, such as bromocriptine and cabergoline. Surgical treatment, in the form of trans-sphenoidal pituitary adenectomy, is indicated for macroprolactinomas but is associated with risks including panhypopituitarism and cerebrospinal fluid leakage.

Non-prolactin-secreting tumours are treated surgically in combination with radiotherapy.

Primary hypothyroidism causing hyperprolactinaemia is treated with thyroid replacement therapy.

Hypergonadotrophic hypogonadism

Hypergonadotrophic hypogonadism or premature ovarian failure is defined as menopause occurring before the age of 40 years. It may be due to various causes:

- chromosomal abnormalities (e.g. mosaic Turner's syndrome);
- autoimmune disease: autoantibodies are detected against ovarian cells, gonadotrophin receptors and/or the oocytes. Often, premature ovarian failure occurs in association with other autoimmune disorders, such as diabetes mellitus, hypothyroidism and Addison's disease;
- infection (e.g. mumps oophoritis);
- previous surgery, radiotherapy or chemotherapy; or
- idiopathic.

The only treatment option for patients with premature ovarian failure is in-vitro fertilization (IVF) with donor eggs. In terms of their long-term management, they should be offered hormone replacement therapy to protect their skeleton and cardiovascular system from the effects of hypo-oestrogenism.

Hypogonadotrophic hypogonadism

Hypogonadotrophic hypogonadism is a state of gonadal dysfunction, characterized by hypo-oestrogenaemia, anovulation and amenorrhoea, due to anatomical and/or functional disorders of the hypothalamus/pituitary gland. In

hypogonadotrophic hypogonadism, there is a deficient secretion of GnRH and/or FSH and LH. Patients present with primary or secondary amenorrhoea and infertility.

Its causes can be either congenital or acquired. Kallman's syndrome is one of the congenital causes. It consists of isolated gonadotrophin deficiency and anosmia. The syndrome is usually sporadic but it can also be inherited (see Chapter 16).

Acquired causes of hypogonadotrophic hypogonadism include:

- central nervous system tumours, i.e. space-occupying lesions around the hypothalamus or the pituitary that disrupt gonadotrophin secretion. The most common of these tumours is craniopharyngioma;
- Sheehan's syndrome, i.e. pituitary necrosis due to massive obstetric haemorrhage with hypovolaemic shock;
- postradiation hypothalamic dysfunction;
- isolated GnRH deficiency;
- inflammatory or infiltrative processes of the pituitary;
- pituitary infarction
- eating disorders (anorexia nervosa) with excessive weight loss;
- stress; and
- excessive exercise.

In patients with hypogonadotrophic hypogonadism, ovulation is restored with the administration of gonadotrophins. Pulsatile GnRH is only indicated in the presence of intact pituitary function.

If a central nervous system tumour is present, surgery is indicated.

Patients with anorexia nervosa may benefit from weight gain and psychotherapy. Nevertheless, in cases of persistent anovulation despite adequate weight gain, gonadotrophins or pulsatile GnRH can be considered.

Normogonadotrophic hypogonadism

This category includes women with anovulation with normal FSH, LH and prolactin levels. They may present with regular menses, oligomenorrhoea or even amenorrhoea. Predomi-

nantly, this group comprises women with PCOS. This is discussed in more detail in Chapter 18.

Other causes of normogonadotrophic hypogonadism and hyperandrogenism include:

- late-onset congenital adrenal hyperplasia;
- adrenal tumours; and
- androgen-producing ovarian tumours (see Chapter 26).

In the presence of PCOS, obese patients will benefit from weight loss. This will not only improve their response to ovulation induction, but may also lead to resumption of spontaneous ovulation. The pharmacologic agent most commonly used for ovulation induction in women with PCOS is clomiphene citrate (CC). If patients fail to respond to it, gonadotrophins or insulin-sensitizing agents may also be used. Laparoscopic ovarian drilling has also been used for PCOS patients unresponsive to CC.

A summary of investigations, classifications and treatments is shown in Figure 17.3, and an overview of assessments and treatments is given in the guidelines of the National Institute for Health and Clinical Excellence (2004).

Medical Induction of Ovulation

Effective use of drugs used to induce ovulation comes from an in-depth understanding of their mechanism of action.

Antioestrogens

Non-steroidal selective oestrogen receptor modulators, including CC and tamoxifen, are used for ovulation induction. It is thought that they bind with oestrogen receptors in the hypothalamus, leading to a perceived drop in the endogenous oestrogen levels. As a consequence, GnRH and endogenous gonadotrophin secretion is increased, leading to induction of ovulation. Figure 17.4 shows the structure of the drugs.

Clomiphene citrate

CC is the most commonly used ovulation induction agent, and most evidence on the efficacy of antioestrogens derives from its use, since its introduction in 1962.

Pharmacology/mechanism of action

CC is a non-steroidal triphenylethylene derivative with both oestrogenic and antioestrogenic properties; nevertheless, it mainly acts as an antioestrogen.

Indications for treatment

CC is the drug of choice for anovulatory infertile women with WHO Group II ovulation disorder, that is women with oligo- or amenorrhoea, with or without hyperandrogenism, and normal levels of prolactin, oestrogen and thyroid hormones. Typically, this group includes women with PCOS.

CC has also been tried for the treatment of unexplained infertility. Nonetheless, when CC treatment was compared with placebo or no treatment, there was no evidence that CC was more effective in this subgroup of infertile women (Hughes et al 2000).

Treatment regimens and monitoring

CC treatment is typically started with a daily dose of 50 mg, from day 2 of the cycle, for a total of 5 days. For amenorrhoeic women, treatment can be commenced at any time, provided pregnancy has been excluded or following a progestogen challenge test. Different regimens have also been tried, and overall CC treatment can safely be initiated anywhere between days 2 and 5 of the cycle for a total period of 5 days. Ovulation usually occurs 5–10 days after the course of treatment has been completed.

If ovulation is not induced with the initial dose of 50 mg, the dose of CC can be increased in 50-mg increments in subsequent cycles up to a maximum dose of 250 mg/day. Approximately 70% of anovulatory women treated with CC respond to a dose of 100–150 mg/day (Gysler et al 1982). In practice, doses of 250 mg are rarely used. Women who do not ovulate while taking a dose of 150 mg are considered

Figure 17.4 Structure of oestradiol and antioestrogen derivatives used in ovulation induction.

to be 'clomiphene-resistant' (Vandermolen et al 2001). The required CC dose is correlated to body weight, as there is a significant association between CC treatment failure and BMI greater than 27 kg/m². Women who are overweight should be advised that a 5% reduction in weight may improve endocrine and ovarian function, increase spontaneous conception rates and improve the response to CC treatment. Lower doses of 25–50 mg/day should be considered for those women who are exceptionally sensitive to treatment with CC.

Monitoring of CC treatment is recommended. Ovulation is confirmed either with serum progesterone measurements or with the use of transvaginal ultrasonography. Serum progesterone concentrations are measured during the luteal phase. Ultrasound monitoring should be offered at least during the first treatment cycle to ensure that the woman is on the lowest necessary dose to achieve ovulation (National Institute for Health and Clinical Excellence 2004). Monitoring will minimize the risk of multiple pregnancy and ovarian hyperstimulation syndrome (OHSS), and is essential in patients in whom ovulation does not seem to have been induced.

Results

Studies with CC have shown an ovulation rate of 60–85% and a pregnancy rate of 30–40%. The discrepancy between ovulation and fecundity rates has not been explained, but may be due to other coexisting fertility factors, such as endometriosis or tubal damage. Some argue that it may be associated with possible antioestrogenic effects that CC exhibits on the endometrium and cervical mucus (Milson et al 2002).

A systematic review of 12 randomized controlled trials supported the effectiveness of CC therapy for anovulatory infertile women (Beck et al 2005). Clomiphene was found to be effective in increasing pregnancy rate compared with placebo [fixed odds ratio (OR) 5.8, 95% confidence interval (CI) 1.6–21.5; number needed to treat (NNT) 5.9, 95% CI 3.6–16.7].

Cumulative conception rates continue to rise after six cycles of treatment, reaching a plateau after 12 cycles. However, prolonged treatment with CC may be associated with an increased risk of ovarian malignancy. Therefore, after completion of 12 cycles of treatment, alternative therapies ought to be considered (National Institute for Health and Clinical Excellence 2004). Factors associated with increased risk of CC treatment failure include increased maternal age, raised BMI and history of severe oligomenorrhoea (Milson et al 2002).

Side-effects

Side-effects with CC treatment are common, but usually mild and transient. Hot flushes and other vasomotor symptoms may occur in up to 10% of patients. Other symptoms include abdominal pain, nausea, vomiting, breast tenderness, headache, insomnia and hair loss. Rarely, visual disturbances (scotomata, blurred or doubled vision) may occur. In the latter case, CC should be discontinued and ophthalmology assessment arranged if symptoms do not cease.

Risks of treatment

With CC therapy, the risk of multiple gestation is approximately 2–13% (Venn and Lumley 1994). OHSS may occur in approximately 13% of cases, whereas severe OHSS is rare. Counselling of women undergoing ovulation induction with CC regarding the above risks is, therefore, essential.

The incidence of spontaneous miscarriage is 13–25% (Milson et al 2002). This figure is no different from the incidence of miscarriage in spontaneous conceptions. In addition to this, there is no evidence to indicate that CC treatment is associated with a higher incidence of congenital abnormalities.

Adjuvant treatment

A systematic review of 12 randomized controlled trials (Beck et al 2005) examined the concomitant administration of CC with other agents to infertile anovulatory women. The use of clomiphene in combination with tamoxifen did not provide any evidence of increased effect on pregnancy rate compared with clomiphene alone. The results were similar when CC plus ketoconazole was compared with CC alone, and CC plus bromocriptine was compared with CC alone.

However, clomiphene plus dexamethasone treatment resulted in a significant improvement in pregnancy rate (fixed OR 11.3, 95% CI 5.3–24.0; NNT 2.7, 95% CI 2.1–3.6) compared with clomiphene alone, as did clomiphene plus pretreatment with combined oral contraceptives (fixed OR 27.2, 95% CI 3.1–235.0; NNT 2.0, 95% CI 1.4–3.4).

Tamoxifen

Tamoxifen is a triphenylethylene derivative structurally similar to CC. It has been widely used in the treatment of breast cancer. In ovulation induction, tamoxifen is administered in doses of 20–80 mg/day, from day 2 to day 6 of the cycle. Tamoxifen, unlike CC, does not exhibit any antioestrogenic effects on the endometrium or vaginal mucosa. Therefore, it was thought that its use might be superior to CC.

Preliminary research has shown that tamoxifen has similar ovulation (44% with tamoxifen vs 45% with CC) and pregnancy rates (22% with tamoxifen vs 15% with CC) (Boostanfar 2001, Gerhard and Runnebaum 1979) compared with CC.

A meta-analysis, involving four trials, compared tamoxifen with CC in anovulatory women and showed that the two drugs were equally effective. Both drugs resulted in similar ovulation rates (OR 0.755, 95% CI 0.513–1.111). No benefit of tamoxifen over CC in achievement of pregnancy per cycle (OR 1.056, 95% CI 0.583–1.912) or per ovulatory cycle (OR 1.162, 95% CI 0.632–2.134) was demonstrated (Steiner et al 2005).

One randomized controlled trial showed that combination therapy of tamoxifen with CC did not improve pregnancy rates [8.6% with tamoxifen/CC vs 4.8% with CC alone; relative risk (RR) 1.80, 95% CI 0.20–16.21] (Suginami 1993).

In most units, tamoxifen is utilized as a second-line therapy in patients who experience side-effects on CC or who appear non-responsive.

Letrozole

Letrozole, an aromatase inhibitor, may be an alternative option for clomiphene-resistant anovulatory women. It has even been suggested that letrozole could be used as a first-line ovulation induction agent instead of CC. However, experience with this medication remains limited, and further research is needed to establish its role, utility and safety.

Pharmacology and mechanism of action

Aromatase inhibitors were initially introduced for the treatment of breast cancer. Aromatase is a cytochrome P-450 haemoprotein that catalyses the rate-limiting step in the production of oestrogens using androgens as a substrate. Letrozole is a highly potent, selective and reversible aromatase inhibitor (Bayar et al 2006). Letrozole inhibits peripheral oestrogen production and, therefore, stimulates endogenous FSH secretion. Moreover, the accumulated androgens may increase follicular sensitivity to FSH (Mitwally and Casper 2004). Its high oral bioavailability and short half-life make it a suitable agent for ovulation induction. One potential advantage of letrozole over CC is its lack of direct antioestrogenic effects on the cervical mucus,

the endometrium, uterine blood flow and embryo development (Barroso et al 2006).

Results

In a Cochrane review, Cantineau et al (2007) identified five trials comparing aromatase inhibitors with antioestrogens used as ovulation induction agents in ovarian stimulation protocols for intrauterine insemination (IUI) in subfertile women. No benefits of letrozole use were identified. Other studies involving women with anovulation or unexplained infertility have shown comparable pregnancy rates between letrozole and CC (Barroso et al 2006, Bayar et al 2006, Davar et al 2006, Jee et al 2006). One study reported higher pregnancy rates in PCOS patients treated with letrozole (Atay et al 2006). Results from larger randomized controlled trials are needed to determine the role of letrozole in ovulation induction.

Dopamine Agonists

Pharmacology and mechanism of action

Prolactin secretion from the anterior pituitary is mainly regulated by the inhibitory control of dopamine. Therefore, drugs that exhibit a dopaminomimetic activity reduce prolactin serum concentrations and restore gonadal function in hyperprolactinaemic women, with or without a pituitary adenoma. If a prolactinoma is present, dopamine agonists may also reduce tumour size (see Chapter 16).

The two most commonly used dopamine agonists are bromocriptine and cabergoline. Both medications are ergot alkaloids that mimic dopamine's actions as they bind to dopamine receptors. Bromocriptine's serum concentrations peak 1–3 h after oral administration, but very little remains in the circulation after 14 h. Cabergoline is a longer-acting dopamine agonist with a higher affinity for the dopamine receptors than bromocriptine. A single dose of cabergoline inhibits prolactin secretion for 7 days.

A newer dopamine agonist licensed for the treatment of hyperprolactinaemia is quinagolide. Quinagolide is a non-ergot dopamine D₂ agonist. It has a longer biological half-life than bromocriptine.

Indications for treatment

Dopamine agonists are the treatment of choice for infertile women with hyperprolactinaemia. Nevertheless, if ovulation is not achieved despite establishment of euprolactinaemia, adjuvant therapy with CC or gonadotrophins must be considered.

It has been observed that approximately 30% of patients with PCOS show hyperprolactinaemia. In these patients, adjuvant therapy with dopamine agonists may be considered. The pathophysiology behind this remains unclear.

Regimen, monitoring and results

Bromocriptine is the most widely used preparation. Treatment starts at a low dose and is increased gradually. The initial dose should be low in order to minimize gastrointestinal and cardiovascular side-effects. Usually, therapy is

initiated with 1.25 mg bromocriptine given at bedtime to suppress the nocturnal prolactin secretion. The dose is gradually increased until the dose required to maintain normal prolactin levels has been established. The usual daily dose is 7.5 mg in divided doses, increased if necessary to a maximum of 30 mg/day. Serum prolactin concentrations must be monitored regularly, and ovulation is monitored with serum progesterone concentrations. Ovulation is usually monofollicular, and ultrasound monitoring of follicle size and numbers is unnecessary if ovulation and regular menses are induced.

Women with a microprolactinoma who are planning to conceive should be prescribed bromocriptine. If pregnancy occurs, bromocriptine may be discontinued as the risk of tumour growth is very small (2%). Nevertheless, in the case of macroprolactinomas, the risk of growth is significant (25%) and treatment with bromocriptine should be continued throughout pregnancy (Balen 2004). Monitoring of these women is done clinically, based on symptoms such as headaches and visual disturbances, and will include visual field assessments and management jointly with an endocrinologist.

Cabergoline treatment is initiated at 500 µg/week, either as a single dose or as two divided doses on separate days. Prolactin levels must be monitored monthly and cabergoline dosage increased, if necessary, at monthly intervals. The usual therapeutic dose is 1 mg/week, ranging from 0.25 to 2 mg/week. The manufacturer advises discontinuation of the drug during pregnancy.

Quinagolide treatment should also be initiated at a low dose. Usually, it is commenced at 25 µg given at bedtime for 3 days. Then, it is increased at 3-day intervals in steps of 25 µg. The usual maintenance dose is 75–150 µg/day. The manufacturer advises discontinuation of the drug during pregnancy, unless medical reasons for continuing arise.

With the use of dopamine agonists, euprolactinaemia is achieved in approximately 60–85% of women. Regular menses are restored in 70–90% of cases and ovulation in 50–75%. If a prolactinoma is present, a decrease in tumour size is achieved in 70% of patients. Pregnancy rates of 30–70% have been reported overall.

Two large randomized controlled trials compared cabergoline with bromocriptine in women with hyperlactinaemic amenorrhoea. Cabergoline was found to be more effective than bromocriptine in achieving euprolactinaemia (83% and 93% with cabergoline vs 59% and 48% with bromocriptine). Moreover, cabergoline was more effective in restoring ovulation and increasing pregnancy rates (72% and 72% with cabergoline and 52% and 48% with bromocriptine) (Webster et al 1994, Pascal-Vigneron et al 1995). Nevertheless, consideration must be given to safety for use in pregnancy (National Institute for Health and Clinical Excellence 2004).

Side-effects

Side-effects of dopamine agonist treatment are common, but are usually mild and transient. Approximately 5% of patients will discontinue treatment for this reason. Side-effects are mainly gastrointestinal and cardiovascular. Gastrointestinal side-effects include nausea, vomiting and constipation. Other side-effects include drowsiness, orthostatic hypoten-

sion, headaches and nasal congestion. Side-effects can be minimized if treatment is initiated at a low dose and then gradually increased. Moreover, vaginal administration of the medication may help. The incidence of side-effects is lower with cabergoline than with bromocriptine.

With dopamine agonists, there is no increase in the risk of OHSS, multiple pregnancy or spontaneous miscarriage.

Insulin-Sensitizing Agents

PCOS is characterized by chronic anovulatory infertility and hyperandrogenism with clinical manifestations of oligo- or amenorrhoea, hirsutism and acne. Women with PCOS exhibit an increased prevalence of cardiovascular risk factors, including a higher incidence of obesity, insulin resistance and hyperinsulinaemia (Royal College of Obstetricians and Gynaecologists 2007). Increased insulin concentrations lead to hyperandrogenism and subsequently anovulation. In obese (BMI >30 kg/m²) PCOS women, weight reduction alone may decrease hyperinsulinaemia and hyperandrogenism, and restore ovulation. Therefore, prior to commencing drug treatment, women should be advised to lose weight, as this would improve their chance of spontaneous ovulation and improve their response to ovulation induction.

Metformin

Insulin-sensitizing agents have been tried as ovulation induction drugs in PCOS patients. The most commonly used is metformin, a biguanide oral hypoglycaemic drug used for the treatment of type 2 diabetes mellitus. Metformin has been proven to reduce serum insulin and androgen concentrations, and improve ovulation rates and hirsutism (Lord et al 2003). Metformin has been used as an ovulation induction agent in many trials; nevertheless, these trials are characterized by heterogeneity in terms of dosage, timing and duration of treatment (Al-Inany and Johnson 2006).

A Cochrane review, including women with clomiphene-resistant PCOS and a mean BMI greater than 25 kg/m², concluded that metformin as a single agent did not increase pregnancy rates compared with placebo. Treatment with both metformin and CC did increase clinical pregnancy rates compared with CC alone (OR 4.88, 95% CI 2.46–9.67). Metformin as a single agent was, however, shown to induce ovulation compared with placebo (OR 3.88, 95% CI 2.25–6.69). Moreover, metformin in combination with CC was more effective at inducing ovulation compared with CC alone (OR 4.41, 95% CI 2.37–8.22) (Lord et al 2003).

Two large randomized controlled trials (Moll et al 2006, Legro et al 2007) concluded that metformin should not be used as a primary method for ovulation induction in PCOS patients. Moll et al (2006) compared the effect of CC plus metformin and CC plus placebo on ovulation induction in PCOS women. They concluded that there were no significant differences in ovulation, ongoing pregnancy or miscarriage rates. Nevertheless, a large proportion of women in the metformin group discontinued treatment because of side-effects. Legro et al (2007) compared CC plus placebo, metformin plus placebo and CC plus metformin. The livebirth rate was 22.5% in the CC group, 7.2% in the metformin group and 26.8% in the combination group. Conception rates were

lower in the metformin group (21.7%) than in the CC group (39.5%) or the combination group (46%).

Therefore, infertile women with PCOS should not be offered metformin as a first-line agent, and CC remains the drug of choice. Nonetheless, PCOS patients who have not responded to CC and who have a BMI greater than 25 kg/m² should be offered combined metformin and CC treatment (National Institute for Health and Clinical Excellence 2004).

It must be noted that metformin has not been licensed in the UK for use in women who are not diabetic. Therefore, careful counselling of women is mandatory prior to commencing treatment with metformin.

Treatment with metformin is mainly associated with gastrointestinal side-effects, including nausea, vomiting, diarrhoea and abdominal cramps. Lactic acidosis is a rare event. No evidence of fetal toxicity or teratogenicity has been reported.

Other drugs

Other insulin-sensitizing agents tried in the management of anovulatory infertility include the thiazolidinedione hypoglycaemic drugs. Experience with these drugs in PCOS women is limited. Troglitazone was shown to be effective in inducing ovulation. Nevertheless, it was withdrawn from the market after reports of hepatotoxicity. Rosiglitazone and pioglitazone are newer drugs used for the treatment of type 2 diabetes mellitus. Regular monitoring of liver enzymes is recommended, as these drugs may also have hepatotoxic effects. These agents are 'class C' drugs with evidence of teratogenicity in animals (Lord et al 2003), and far more data are required in ovulation induction patients to determine their potential role and safety.

Pulsatile Gonadotrophin-Releasing Hormone

Pulsatile GnRH has been used for ovulation induction since 1980. It is the treatment of choice for women with hypogonadotrophic hypogonadism with an intact pituitary function (Braat et al 1991).

Mechanism of action

In patients with hypogonadotrophic hypogonadism, the administration of exogenous pulsatile GnRH restores normal pulsatile pituitary gonadotrophin secretion. Subsequently, follicular recruitment and growth proceed as in a normal menstrual cycle, leading to the development of a single dominant follicle (Martin et al 1993).

Regimen and monitoring

Pulsatile GnRH is administered via a portable mini-pump, either intravenously or subcutaneously. This pump must be worn continuously throughout the treatment. A 2.5–20.0 µg/bolus is administered via the pump at 60–90-min intervals. The treatment starts at a low dose (2.5–5.0 µg/pulse) and is gradually increased until ovulation is achieved. The intravenous route is preferred by some authors as it mimics the physiological spikes of the hormone and, therefore, is more

physiological, requires lower doses and is more cost-effective than the subcutaneous route of administration.

Monitoring is performed with regular serum oestradiol measurements and pelvic ultrasound every 3–4 days. The luteal phase is supported either by continuing the same pulsatile GnRH regimen or with the administration of exogenous human chorionic gonadotrophin (hCG).

Results

Pulsatile GnRH is a highly effective method of ovulation induction. Ovulation rates and pregnancy rates per treatment cycle of 70–93% and 18–29% have been reported (Baat et al 1991, Martin et al 1993, Filicori et al 1994).

Nevertheless, ovulation induction with pulsatile GnRH has been less successful in women with PCOS, raised BMI and high serum LH, testosterone or insulin levels (Filicori et al 1994).

Twin pregnancy rates ranged between 3.8% and 13.5% (Baat et al 1991, Martin et al 1993, Filicori et al 1994). This risk is significantly lower than that associated with gonadotrophin treatment (approximately 15%) (Martin et al 1993). Higher order pregnancies are rarely seen with pulsatile GnRH therapy.

The risk of OHSS is very low when exogenous GnRH is used. In comparison with gonadotrophin ovulation induction, GnRH treatment is associated with a lower risk of multiple folliculogenesis and ovarian enlargement (Martin et al 1993).

Spontaneous miscarriage rates have been approximately 10–30%. These appear to be higher in PCOS patients (40%) and lower in women with hypogonadotrophic hypogonadism (20%) (Filicori et al 1994). It is believed that in PCOS women, pretreatment with GnRH analogues may improve outcomes and lower the incidence of multiple pregnancies. Nonetheless, a systematic review by Bayram et al (2004) found no evidence to support the use of pulsatile GnRH in clomiphene-resistant PCOS women.

Side-effects

Overall, exogenous pulsatile GnRH is simple to use, does not require expensive monitoring and is associated with lower risks of multiple pregnancy and OHSS in comparison with gonadotrophin treatment. Nevertheless, many women are reluctant to use this treatment as it requires maintenance of an indwelling cannula for a long period of time; moreover, cases of infection at the site of the cannula have been reported. These seem to be more serious with the intravenous route of administration, whilst the subcutaneous route is mainly associated with local inflammation at the site of needle insertion.

Gonadotrophins

Since the 1960s, exogenous gonadotrophins have been used for ovulation induction in women with WHO Group I and II anovulatory infertility. Gonadotrophins are considered highly effective in inducing ovulation in these groups of patients. Nevertheless, their use has been associated with risks of multiple pregnancy and ovarian hyperstimulation.

Preparations

A number of preparations of exogenous gonadotrophins exist but not all are still available in every country.

Urinary human menopausal gonadotrophin

Human menopausal gonadotrophin (hMG, Menotropin) derives from the urine of postmenopausal women. It contains equal amounts of FSH and LH (75 IU of each), as well as other urinary proteins (>95% of total protein content). The initial preparations were crude as they contained significant amounts of non-gonadotrophin proteins; moreover, they had to be administered intramuscularly. Newer hMG preparations are more purified, contain fewer proteins and can be administered subcutaneously.

Urinary follicle-stimulating hormone

Purified urinary FSH was first introduced in the 1980s (Urofollitropin). It was developed after removing LH by using monoclonal antibody technology (immunoaffinity chromatography). Purified urinary FSH contains 75 IU FSH and less than 1 IU LH. Still-significant amounts of non-gonadotrophin proteins were present and the preparation had to be given intramuscularly. Newer preparations are more highly purified, contain less than 0.001 IU LH and can be given subcutaneously, allowing self-administration.

Recombinant follicle-stimulating hormone

Recombinant FSH was developed by genetic engineering in 1988. Through recombinant DNA techniques, the genes responsible for expression of the α and β subunits of FSH were introduced to the genome of a Chinese hamster ovary cell line. These cells would then produce FSH. The synthesized FSH is purified using chromatography. In comparison with urinary FSH, recombinant FSH has the same structure of side chains, but contains more basic and less acidic isoforms. Its pharmacokinetic characteristics are similar to those of urinary FSH.

Recombinant luteinizing hormone

Recombinant LH was only introduced recently. Its production is based on the same principles of genetic engineering that apply to the synthesis of recombinant FSH. Its pharmacokinetics are similar to those of human pituitary LH.

Urinary human chorionic gonadotrophin

Urinary hCG is extracted from the placenta or the urine of pregnant women. It is used in gonadotrophin-stimulated cycles to be a surrogate for the LH surge and to trigger ovulation once a follicle reaches maturation. The preparation is administered either intramuscularly or subcutaneously.

Recombinant human chorionic gonadotrophin

Recombinant hCG is also available. Studies suggest that 250 μ g recombinant hCG is equivalent to 5000–10,000 IU urinary hCG.

Thus far, research indicates that different gonadotrophin preparations are equally effective. When recombinant hCG

was compared with urinary hCG, no differences in clinical outcomes (including ongoing pregnancy and livebirth rates, miscarriage and OHSS rates) were demonstrated (Al-Inany et al 2005). When recombinant FSH was compared with urinary hMG, no significant differences in pregnancy rates were observed (Nugent et al 2000).

Nevertheless, recombinant gonadotrophins have certain advantages in comparison with urinary products. They have high batch-to-batch consistency, unlimited supply, high purity and are associated with less risk of allergic reaction as they do not contain any non-gonadotrophin proteins. However, their increased cost is a major disadvantage. Thus, when deciding which preparation to use, factors such as patient safety, cost and drug availability must be taken into consideration (Table 17.1)

Indications

Ovulation induction with gonadotrophins is indicated for:

- women with WHO Group I anovulatory infertility (hypogonadotrophic hypogonadism);
- women with WHO Group II anovulatory infertility (including women with PCOS) who failed to ovulate on CC; and

- women with unexplained infertility or ovulatory women undergoing IUI for unexplained or mild male factor infertility.

The choice of therapeutic regimen will depend on the underlying cause of infertility. Treatment must be tailored to the individual's needs.

Hypogonadotrophic hypogonadism

Women with hypogonadotrophic hypogonadism have extremely low levels of endogenous gonadotrophins. Therefore, both exogenous FSH and LH are required. FSH is essential for follicular growth and oocyte maturation, whereas LH is required for steroidogenesis, luteinization and ovulation. The treatment of choice for this group of patients is hMG, as it contains both FSH and LH (Shoham et al 1991). Nonetheless, the use of recombinant FSH and LH may be an alternative. The regimen used for these women is the 'step-up protocol'. The luteal phase is usually supported with the administration of hCG, as these patients have very low levels of LH.

Polycystic ovary syndrome

Clomiphene-resistant PCOS women may be candidates for treatment with gonadotrophins. In contrast to women with hypogonadotrophic hypogonadism, PCOS patients have FSH and LH levels which are normal or may be elevated. These patients are at increased risk of multiple pregnancy and OHSS. Therefore, relatively low doses of gonadotrophins are needed for ovulation induction. The protocols used for this category of patients are the 'chronic low-dose step-up protocol', the 'step-down' protocol and the 'sequential protocol'. Luteal phase support is not routinely required but, if needed, progesterone support is preferred.

A systematic review of 14 randomized controlled trials found that urinary hMG and urinary FSH had similar effectiveness in terms of pregnancy rates. However, the incidence of OHSS was reduced with FSH compared with hMG. No significant differences were reported between the use of subcutaneous pulsatile and intramuscular injection of gonadotrophins, daily or alternate-day administration, and 'step-up' or 'standard' regimens (Nugent et al 2000).

A Cochrane review including four randomized controlled trials concluded that when recombinant FSH was compared with urinary FSH, there were no significant differences in terms of ovulation, pregnancy, miscarriage, multiple pregnancy and OHSS rates. No significant differences were demonstrated between administering recombinant FSH as a chronic low dose or as a standard regimen (Bayram et al 2001). The reader is referred to the review by Amer (2007) for further information.

Ovulatory patients undergoing intrauterine insemination

Gonadotrophins have been used for superovulation induction in women with unexplained infertility or ovulatory women with age-related or mild male factor infertility undergoing IUI. In these women, both the step-up and step-down regimens have been applied. The purpose of gonadotrophin treatment is to induce multifollicular development

Table 17.1 Preparations of gonadotrophins for ovulation induction

Formulation	Proprietary Name	Administered
Urinary		
Human menopausal gonadotrophin FSH 75 U and LH 75 U/ampoule	Merional Menopur	IM SC
Urofollitrophin FSH 75 U and LH <1 U/ampoule	Fostimon	IM/SC
Human chorionic gonadotrophin 5000 U/ampoule	Choragon Pregnyl	IM/SC
Recombinant		
Follitrophin α FSH 75 U/ampoule	Gonal-F	SC
Follitrophin β FSH 75 U or multiples in cartridges	Puregon	SC
Lutrophin α LH 75 U/ampoule	Luveris	SC
Follitrophin α with lutrophin α FSH 150 U and LH 75 U	Pergoveris	SC
Choriogonadotrophin α 6500 U \equiv 250 μ g	Ovitrelle	SC

FSH, follicle-stimulating hormone; LH, luteinizing hormone; IM, intramuscular; SC, subcutaneous.

('superovulation'). Careful monitoring is essential as the risks of OHSS and multiple pregnancy are high.

Regimens and monitoring

Varying regimens of administering exogenous gonadotrophins have been developed (see Figure 17.5).

Step-up protocol

The step-up protocol is used for women with hypogonadotrophic hypogonadism and for clomiphene-resistant PCOS patients.

Women with WHO Group I anovulation (hypogonadotrophic hypogonadism) are initially given a daily dose of 150 IU hMG. The dose is increased by 75 IU after 4–5 days depending on the response. This is assessed by serum oestradiol concentration and transvaginal ultrasonography. If an ovarian response is confirmed, the gonadotrophin dose is not altered. The frequency of monitoring may be intensified, depending on oestradiol levels and the size or number of the growing follicles. When one or two follicles reach a mean diameter of 18 mm, 5000–10,000 IU hCG is administered to trigger ovulation. Ovulation usually occurs after 36–48 h and couples are advised to have intercourse on the day of the injection and the day after. This regimen is also known as the 'regular-dose step-up protocol'.

In women with PCOS, the 'chronic low-dose step-up protocol' is preferred. Treatment is initiated with a low FSH dose (50–75 IU) continued for a longer period (14 days). Small increments are allowed (25–37.5 IU every 5–7 days) until a dominant follicle emerges.

Step-down protocol

In this regimen, treatment is initiated at higher doses of FSH and then gradually reduced. The purpose of this approach is to mimic the FSH fluctuations during the normal ovulatory cycle. Therapy is commenced at 150 IU/day on day 2 or 3 of the cycle. When a dominant follicle emerges, FSH is reduced by 37.5 IU/day. After 2–3 days, FSH is further decreased to 75 IU/day. This last dose is continued until hCG is administered to trigger ovulation.

Sequential protocol

Treatment is started with a 'step-up' protocol, followed by a 'step-down' regimen once a dominant follicle (≥ 14 mm) has emerged.

Concomitant use of gonadotrophin-releasing hormone agonist

Combined treatment with a GnRH agonist and gonadotrophins has been used in PCOS women undergoing IVF. In ovulation induction, pretreatment with a GnRH agonist may theoretically suppress endogenous LH levels. If this treatment is continued during gonadotrophin administration, premature luteinization may be prevented.

In a randomized clinical trial when GnRH agonists were used concomitantly with gonadotrophins, no significant differences were shown in ovulation or pregnancy rates compared with using gonadotrophins alone (Vegetti 1998). Moreover, Nugent et al (2000) found an increase in the incidence of OHSS when GnRH analogues were added to gonadotrophins. Therefore, the use of GnRH agonists is not recommended for PCOS women undergoing ovulation induction with gonadotrophins.

Results

In women with WHO Group I ovulation dysfunction, pregnancy rates of 25% per cycle and cumulative pregnancy rates of 90% after six cycles of treatment have been achieved (Amer 2007). Nevertheless, success rates were lower in PCOS women (5–25% and 30–60%, respectively).

Risks

Treatment with gonadotrophins is associated with an increased risk of multiple pregnancy and OHSS. These complications will be discussed in more detail later in this chapter.

When non-purified preparations are used, their administration may be associated with an increased risk of local reaction (at the injection site) or, on rare occasions, with a severe anaphylactic reaction. In this case, consideration should be given to switch to recombinant gonadotrophin preparations.

Weight Reduction

Obesity has been described as the new worldwide health epidemic. In the UK, obesity affects 24% of the adult female population. As the number of obese women is increasing,

so is the prevalence of the disease among those who seek fertility treatment.

Obesity has been associated with a number of reproductive disorders. These include menstrual disorders, infertility, miscarriage and obstetric complications, both fetal and maternal. It appears that it is not only the increased amount of fat *per se*, but also the fat distribution that is related with these disorders. Thus, an increased waist:hip ratio has a more important effect on fertility than weight alone.

The exact mechanism through which obesity impairs ovarian function, and thus fertility, is largely unknown. It seems that obesity causes low sex-hormone-binding globulin concentrations, hyperandrogenaemia and hyperinsulinaemia. Adipose tissue affects gonadal function via the secretion of adipokines. These include leptin, adiponectin, ghrelin and resistin. The most investigated of all is leptin. Obese women have elevated serum and follicular fluid leptin concentrations. High leptin levels cause a reduction in insulin-induced steroidogenesis in granulosa and theca cells. Leptin also inhibits oestradiol production by the granulosa cells. On the other hand, adiponectin levels decrease in obesity, leading to insulin resistance. Thus, hyperinsulinaemia may be due to the effects of low adiponectin levels and increased resistin levels. The resulting hyperandrogenaemia is caused by the inhibition of sex-hormone-binding globulin and insulin-like growth factor binding protein-1.

As far as fertility is concerned, large retrospective studies have shown a link between obesity and anovulation. Anovulation seems to be the result of hyperandrogenaemia and increased levels of leptin. Obese anovulatory women may or may not have PCOS. It is unknown whether obesity leads to PCOS or vice versa.

The impact of obesity on assisted conception techniques has also been investigated. Regarding ovulation induction, it seems that obese women can be more resistant to CC than non-obese women. As far as IVF is concerned, the evidence from the literature is inconclusive. Although obese women appear to require higher doses of drugs for ovarian stimulation, have a lower chance of pregnancy following IVF and an increased miscarriage rate, it is not clear whether there is an effect of BMI on livebirth rates, cycle cancellation, oocyte recovery or ovarian hyperstimulation incidence (Maheshwari et al 2007).

In this group of patients, weight reduction improves biochemical indices and fertility rates. A 5–10% decrease in body weight will lead to a 30% reduction in body fat, which is sufficient to restore regular menstruation and ovulation. A prospective study was conducted by Clark et al (1995). This study looked at the effect of weight loss, with diet and exercise, on women with anovulation, clomiphene resistance and a BMI greater than 30. Weight reduction led to resumption of ovulation and subsequent pregnancy, as well as a reduction of testosterone levels and increased sex-hormone-binding globulin concentrations.

According to the guidelines of the British Fertility Society, it is advised that women with a BMI greater than 35 kg/m² should not receive fertility investigations or treatment until they reduce their BMI to less than 35 kg/m². Women who are trying to conceive should be advised to maintain a BMI in the range of 20–25 kg/m². Women with a BMI greater than 30 kg/m² should be encouraged to lose weight to a BMI less than 30 kg/m² before receiving fertility therapy either in

the form of ovulation induction or as assisted reproduction technology.

Nevertheless, the management of obesity is difficult and requires a multidisciplinary approach. Women should be encouraged to adopt a healthy lifestyle. This would include modification of their dietary quality and change in physical activity. If this fails, pharmacotherapy ought to be considered and, ultimately, obesity surgery. If there is an underlying eating disorder, psychopathology should also be taken into consideration and appropriate referrals made.

Pharmacotherapy includes two main groups of drugs: peripherally acting and centrally acting drugs. The first category mainly infers to orlistat. This medication inhibits gastric and pancreatic lipase and, therefore, reduces fat absorption from the intestine. Orlistat has been shown to decrease testosterone levels in PCOS patients. Although it is generally well tolerated, it can cause gastrointestinal disturbances, which consequently lead to low patient compliance. Orlistat is not licensed for use in pregnancy. The second category of drugs includes sibutramine, which inhibits serotonin and noradrenaline reuptake. It can cause a greater reduction in insulin levels and insulin resistance compared with metformin. Another medication is remonabant, a selective cannabinoid-1 receptor blocker. Both sibutramine and remonabant are contraindicated in pregnancy.

As far as bariatric surgery is concerned, laparoscopic adjustable gastric banding remains the mainstream therapy. Nonetheless, further research is required in order to establish its role in improving fertility. After the procedure, contraception is required until the target weight is reached.

Surgical Management: Laparoscopic Ovarian Drilling

Surgical ovarian wedge resection, introduced in 1939, was the first established treatment for anovulatory PCOS patients. The procedure was performed via laparotomy, and 75% of each ovary was removed. It was speculated that by removing part of the hormone-producing ovarian tissue, androgen and inhibin levels would be reduced. This was followed by an increase in FSH levels and a decrease in LH, leading to spontaneous resumption of ovulation. Nevertheless, the response rate was variable and the procedure was abandoned largely because of the risk of postoperative adhesion formation. As soon as effective medical methods of ovulation became available, ovarian wedge resection became obsolete.

Nonetheless, ovulation induction with CC is not always successful and 20% of women are described as 'CC resistant'. CC-resistant patients can receive treatment with gonadotrophins, but these are relatively expensive, require intensive monitoring and are associated with increased risk of OHSS and multiple pregnancy. Laparoscopic ovarian drilling (LOD) has therefore been introduced as an alternative therapy for this group of patients.

LOD was first described by Gjonnaess in 1984. Both laparoscopic ovarian cautery and laser vaporization (using carbon dioxide, argon or neodymium:yttrium aluminium garnet lasers) have been used since. The aim is to create approximately 10 holes per ovary in the ovarian surface and

stroma. The mechanism of action is thought to be similar to that of ovarian wedge resection. With LOD, androgen-producing ovarian tissue is destroyed. This subsequently causes a decline in the serum levels of androgens, inhibin and LH and an increase in FSH levels. Therefore, disturbances in the ovarian–pituitary feedback mechanism are corrected, leading to follicular recruitment, maturation and ovulation. A long-term cohort study has also shown that up to 20 years after LOD, there was persistence of ovulation and normalization of serum androgens and sex-hormone-binding globulin levels in 60% of the participants (Gjonnaess 1998, Amer et al 2002).

With the employment of LOD, spontaneous ovulation rates of 30–90% and pregnancy rates of 13–88% have been described. In the literature, most data derive from randomized controlled trials comparing ovarian drilling with ovulation induction using exogenous gonadotrophins. There is no evidence of a difference in livebirth outcomes following either LOD (after 6–12 months of follow-up) or three to six cycles of ovulation induction with gonadotrophins in CC-resistant women. Moreover, there was no evidence of a difference in clinical pregnancy rate, miscarriage rate, ovulation rate and quality of life. Nonetheless, multiple pregnancy rates were reduced after LOD (Farquhar et al 2007). Moreover, there appears to be no difference between LOD of one ovary vs drilling of both ovaries in terms of ovulation induction.

In CC-resistant women, LOD may improve clomiphene sensitivity, since when CC or gonadotrophins were added after ovarian drilling, higher pregnancy rates were reported.

Attempts have been made to identify predictors of success in women undergoing LOD, as 43% may not ovulate spontaneously after ovarian drilling. This seems to be related to factors such as the duration of infertility, BMI and free androgen index.

In summary, as there is no evidence of a difference in efficacy between LOD and gonadotrophin ovulation induction, LOD may be the treatment of choice as it is associated with a lower risk of multiple pregnancy and OHSS. Nevertheless, LOD carries risks such as pelvic infection, postoperative adhesion formation, risks of general anaesthesia and the theoretical risk of premature ovarian failure. All these should be taken into consideration before embarking on this procedure. Careful counselling and selection of patients is therefore mandatory. The operation should only be performed by fully trained laparoscopic surgeons. At the moment, the use of LOD is restricted to anovulatory women with a normal BMI. Its use is not recommended as an attempt to decrease the risk of developing diabetes mellitus or coronary artery disease. Long-term risks for women with PCOS (Royal College of Obstetricians and Gynaecologists 2007).

Risks of Induction of Ovulation

Ovarian hyperstimulation syndrome

OHSS is a rare, serious and potentially life-threatening complication of ovulation induction. It is a systemic disease resulting from vasoactive products released from hyperstimulated ovaries. It occurs during the luteal phase of the cycle

or during early pregnancy. The incidence of mild OHSS in ovulation induction with CC is 13.5%, whereas moderate and severe forms have only been described sporadically. In IVF/intracytoplasmic sperm injection (ICSI) cycles, the incidence of mild, moderate and severe OHSS may be 33%, 3–6% and 0.1–2%, respectively (Delvigne and Rozenberg 2002). Only a few cases of OHSS have occurred in spontaneous cycles. The true incidence of mortality from OHSS is unknown; nevertheless, deaths are rare.

Pathophysiology

The pathophysiology of OHSS is characterized by an increased capillary permeability, leading to a shift of fluid from the intravascular to the extravascular space, with third-space fluid accumulation and intravascular dehydration. The exact mechanism remains unknown. It is believed that the increased vascular permeability is the result of vasoactive agents released by the hyperstimulated ovaries. Several agents have been proposed, including oestradiol, LH, prolactin, histamine, prostaglandins, prorenin (renin–angiotensin cascade), serotonin, interleukins and vascular endothelial growth factor.

In the initial stages of OHSS, there is an increase in the size of the ovaries and abdominal discomfort. In more severe forms, ovaries become cystic and there is abdominal distention with pain, nausea, vomiting and diarrhoea. This may be followed by ascites, pleural effusion and, on rare occasions, pericardial effusions. There is marked intravascular volume depletion with haemoconcentration that may lead to severe manifestations, including thromboembolism, severe hypoalbuminaemia, hypovolaemia, oliguria and electrolyte disturbances. Cases of acute respiratory distress syndrome have also been reported. Occasionally, liver impairment may occur.

Diagnosis/classification

The diagnosis of OHSS is based on clinical grounds. A history of ovulation induction accompanied by symptoms of abdominal pain, nausea and vomiting should raise the possibility of OHSS. Other conditions, such as ovarian cyst accidents (e.g. torsion, rupture, haemorrhage), pelvic inflammatory disease and ectopic pregnancy should be considered.

Different classification systems of OHSS have been proposed. The latest system was suggested by Marthur in 2005 and is shown in Table 17.2 as adopted by the Royal College of Obstetricians and Gynaecologists. Four categories of OHSS are noted: mild, moderate, severe and critical. As the management of the condition will be dictated by its severity, it is mandatory to assess each case properly and classify it according to Table 17.2.

Risk factors

Several risk factors of OHSS have been identified in an attempt to prevent this serious iatrogenic complication.

Age

Most studies have reported that women who developed OHSS were significantly younger than those who did not develop OHSS. Women under the age of 30 years are at

Table 17.2 Classification of severity of ovarian hyperstimulation syndrome (OHSS)

Grade	Symptoms
Mild	Abdominal bloating Mild abdominal pain Ovarian size usually <8 cm*
Moderate	Moderate abdominal pain Nausea ± vomiting Ultrasound evidence of ascites Ovarian size usually 8–12 cm*
Severe	Clinical ascites (occasionally hydrothorax) Oliguria Haemoconcentration haematocrit >45% Hypoproteinaemia Ovarian size usually >12 cm*
Critical	Tense ascites or large hydrothorax Haematocrit >55% White cell count >25,000/ml Oligo/anuria Thromboembolism Acute respiratory distress syndrome

*Ovarian size may not correlate with severity of OHSS in cases of assisted reproduction because of the effect of follicular aspiration.

higher risk. A possible explanation could be that ovaries of younger women are more responsive to gonadotrophins, as they contain a higher number of gonadotrophin receptors and a larger number of follicles responding to gonadotrophins.

Allergies

It has been observed that the prevalence of allergies is significantly increased in women who develop OHSS.

Polycystic ovary syndrome

PCOS patients are at high risk. In addition to this, women with 'isolated characteristics of PCO', such as PCO-like ultrasonographic images ('necklace sign'), an LH:FSH ratio greater than 2 or hyperandrogenism are also at increased risk.

Pregnancy

The risk of OHSS is two- to five-fold higher if pregnancy occurs, and may present as a late-onset variant.

Types of stimulatory drugs

Severe OHSS is only rarely associated with clomiphene ovulation induction, whereas moderate forms of the syndrome are encountered in 8% of cycles stimulated with clomiphene. The incidence is much higher when gonadotrophins are used. A study reported that the incidences of mild, moderate and severe OHSS following induction with gonadotrophins are 20%, 6–7% and 1–2%, respectively. GnRH agonists have also been associated with an increase in OHSS incidence. This may be due to inhibition of the spontaneous luteinization process linked with the LH peak.

On the other hand, the use of GnRH antagonists does not increase the risk of OHSS. Insulin-sensitizing agents do not seem to affect its incidence.

Response to ovulation stimulation

High levels of oestradiol, a large number of preovulatory follicles and the presence of large follicles have been associated with an increased risk of OHSS. Other potential predictors of OHSS may include inhibin A and B and vascular endothelial growth factor levels. Further research is required in order to evaluate their positive predictive value and possible future use.

Previous ovarian hyperstimulation syndrome

The risk of developing OHSS is increased in patients who have developed it previously, and altered stimulation protocols need to be utilized.

Prevention

Although several strategies have been developed, OHSS cannot be totally prevented. This mainly applies to late OHSS triggered by the rising serum hCG secreted in early pregnancy. Nevertheless, prevention and early recognition of OHSS are fundamental in ensuring patients' safety. Identification of any risk factors may reduce the risk of developing OHSS, as adaptations can be made to the ovulation regimen. Careful monitoring of the stimulation with the use of ultrasonography should be implemented, as it has a good predictive value in the occurrence of OHSS (Blankstein et al 1987). For instance, starting with a lower dose of gonadotrophin, reducing the dose when OHSS is suspected or even cancelling the cycle and withholding hCG injection may prevent OHSS. In the latter case, the couple should be advised to refrain from intercourse or to use barrier methods of contraception.

Management

OHSS is a rare disease and many healthcare professionals may be unfamiliar with the syndrome. Protocols for the management of OHSS should therefore be in place. Treatment is predominantly supportive, as OHSS resolves spontaneously. Usually, this takes 7 days in non-pregnant women and 10–20 days in pregnant women.

A physical examination, including body weight, abdominal girth measurements, abdominal and cardiorespiratory examination, and assessment of hydration, must be performed. A pelvic ultrasound will help to assess the size of the ovaries and check for ascites. Blood tests should include full blood count, urea and electrolytes, liver function tests and clotting screen. In case of dyspnoea, a chest X-ray or chest ultrasonography should be requested. If pericardial effusion is suspected, an electrocardiogram and echocardiogram will be essential.

Outpatient management

Women with mild OHSS and many with moderate OHSS may be managed as outpatients. Paracetamol and codeine are the analgesics of choice. Non-steroidal anti-inflammatory drugs are contraindicated, as they may compromise renal function. Women should be advised to drink to thirst and not to excess. A review is required every 2–3 days. Nevertheless, urgent reassessment is warranted if the woman develops severe abdominal pain, increasing abdominal

Figure 17.6 Vaginal scan of a patient with moderate ovarian hyperstimulation syndrome, showing enlarged ovary, luteal cysts and ascitic fluid.

distention, dyspnoea or has a subjective impression of decreasing urine output (Royal College of Obstetricians and Gynaecologists 2006).

Inpatient management

Women with severe OHSS and those with moderate OHSS whose symptoms cannot be controlled with oral medication should be admitted to hospital. Critical cases of OHSS may require admission to an intensive care unit for invasive monitoring (see Figure 17.6).

Monitoring of these patients should include:

- heart rate and blood pressure;
- abdominal girth and weight (measured daily);
- intake and output chart;
- daily haemoglobin, haematocrit and platelet count; and
- daily serum creatinine and electrolytes.

Measures of worsening OHSS include: increasing abdominal pain, oliguria (in particular, a persistent positive fluid balance or daily urine output <1000 ml/day), weight gain, increased girth circumference, worsening dyspnoea and haemoconcentration (as measured by raised haemoglobin, haematocrit or white cell count).

If pain is not adequately controlled with paracetamol, oral or parenteral opiates ought to be considered. Nausea is usually caused by the presence of ascites, and measures taken to reduce ascites also contribute to relief from nausea. The recommended antiemetics are those appropriate for early pregnancy, such as metoclopramide, cyclizine and prochlorperazine. The intravascular volume is maintained by encouraging women to drink to thirst. In cases of severe vomiting, intravenous crystalloids, such as normal saline, must be administered, aiming for a fluid intake

of 2–3 l/day. In the case of haemoconcentration, more intensive hydration is needed; if the problem persists, colloid therapy needs to be considered. Colloids that have been used for this purpose include human albumin, dextran, Haemaccel, 6% hydroxyethylstarch and mannitol. Nevertheless, there is no evidence to recommend any specific fluid regimen. Diuretics should be avoided for fear of intravascular volume depletion. In cases of increasing abdominal distention or persistent oliguria, an ultrasound-guided paracentesis should be considered. Drainage of ascitic fluid provides rapid symptomatic relief from pain and dyspnoea, and is followed by a significant improvement in urine output. Intravenous colloid replacement should be considered in order to avoid cardiovascular collapse. Thromboprophylaxis should be given to all women with OHSS who are admitted. This will include full-length venous support stockings and subcutaneous prophylactic heparin. Surgical treatment is reserved for cases of suspected adnexal torsion.

Counselling

Women who undergo ovulation induction should be counselled carefully about the risks and possible symptoms of OHSS. A 24-h contact number and access to a clinician should be offered to these women.

In the case of OHSS, further counselling is needed to provide information and reassurance. For an overview of management of OHSS, the reader is referred to the guidelines of the Royal College of Obstetricians and Gynaecologists (2006).

Multiple pregnancy

In many developed countries, there has been a 30–50% increase in twin births since 1980. Triplet deliveries have increased three- to five-fold during this period. The incidence of multiple births in the UK has risen from 10–15/100,000 maternities before 1981 to 12.1/1000 maternities in 1991 and 14.9/1000 maternities in 2004 (Office for National Statistics 2006). The number of multiple pregnancies conceived is even higher, as spontaneous and iatrogenic fetoreductions are not included in birth statistics.

Multiple pregnancies are high risk as they carry risks for both the mother and the fetus. They are often complicated by preterm delivery, intrauterine growth restriction or a small-for-gestational-age fetus and their sequelae, pre-eclampsia and eclampsia, gestational diabetes, antepartum haemorrhage and assisted delivery. Multiple pregnancies are associated with high infant mortality and morbidity, and carry major long-term consequences for childhood and adult life, especially in terms of neurodevelopmental impairments. Moreover, twin and higher order pregnancies carry significant socioeconomic and psychological consequences for family life.

Approximately 20% of the increase in multiple births can be attributed to advanced maternal age, as it is known that older women are more likely to have a multiple pregnancy. The remainder is associated with ovulation induction and assisted reproductive technologies, such as IVF and ICSI. The exact numbers of higher order pregnancies resulting from ovarian stimulation, with or without IUI, are unknown as

there are no national registers that record the outcome of controlled ovarian stimulation (ESHRE Task Force on Ethics and Law 2003).

Nonetheless, ovarian stimulation, with or without IUI, contributes significantly to the occurrence of multiple births. A study by Lynch et al (2001) showed that 20% of all multiple pregnancies were attributable to ovulation induction agents, which is considerably higher than the 14% attributable to IVF. Similarly, 34% of higher order pregnancies in the UK in 1989 resulted from ovulation induction (Levene et al 1992). Multiple pregnancies occurred in 2–13% of women with all causes of infertility taking CC, whereas women with clomiphene-resistant PCOS treated with gonadotrophins have a multiple pregnancy rate of 36%.

In view of these facts, it is mandatory to design prevention strategies to avoid multiple gestations. In the case of ovarian stimulation, judicious use of ovulation induction drugs and monitoring of the follicular size and number with ultrasonography are essential. In addition to this, ovulation induction ought to be carried out in specialist clinics so that careful monitoring is achieved. Furthermore, specific interventions may reduce the risk of multiple pregnancy. These include withholding the hCG injection and cancelling the cycle, selective aspiration of supernumerary follicles and conversion to IVF cycles. Women who undergo ovulation induction must be counselled regarding the risk of multiple pregnancy and its consequences.

In the event of multiple pregnancy, selective fetal reduction ought to be considered. Multifetal pregnancy reduction (MFPR) refers to 'the termination of one or more normal fetuses in a multifetal pregnancy in order to improve survival rates for the remaining fetuses and decrease maternal morbidity'. For higher order pregnancies, not performing a reduction will increase the risk of losing the pregnancy.

Three different techniques of MFPR have been described. The most commonly used is the transabdominal needle insertion of potassium chloride to the fetal thorax above the diaphragm. This procedure is usually performed at 10–12 weeks of gestation. The selection of the embryo is based on which one is easiest to reach. The second method is the transcervical mini-suction, done between 8 and 11 weeks. Loss of the entire pregnancy has been reported in 50% of cases managed with this technique. The third method consists of transvaginal aspiration of the embryo, usually done at 10–12 weeks (Evans et al 1998).

It is widely accepted that for any higher order multiple pregnancy, reduction to twins has the highest survival rate. Reduction to a singleton pregnancy is not accepted because of the risk of losing that pregnancy if there is a problem later. Women with significant medical disease, such as cardiac disease, or uterine malformations are exceptions to this rule, and reduction to a singleton pregnancy may be considered in such cases (Evans et al 1998).

Prevention of multiple pregnancies should be preferred to MFPR, since it is associated with the ethical dilemmas of abortion. Moreover, it is acknowledged that the original higher order pregnancy may have detrimental effects on the development of the remaining fetuses, in terms of risk of preterm delivery, even after the event of fetocide (ESHRE Task Force on Ethics and Law 2003).

Ovarian cancer

Ovarian cancer is the fourth most common cancer among women in England and Wales, and is the most common cause of gynaecological cancer death. The possibility of a link between ovulation and ovarian oncogenesis led to concerns that fertility treatments may increase the risk of developing ovarian cancer. In particular, the possible association between drugs used for ovulation induction and the risk of ovarian cancer has been the subject of much debate. Concerns have been raised about the effects of multiple ovulations and trauma to the ovarian epithelium (Fathalla 1971), as well as the high levels of gonadotrophins reached during fertility treatment. It has been speculated that the latter may lead to the production of intraovarian carcinogens and malignant transformation (Daly 1992).

A causal relationship between fertility treatment and ovarian cancer was supported by some anecdotal case reports and epidemiological studies. However, other studies showed conflicting results.

A collaborative analysis on data from 12 case-control studies of ovarian cancer conducted in the USA (Whittemore et al 1992) showed that the risk was increased among women who had used fertility drugs (OR 2.8, 95% CI 1.3–6.1) compared with women without a clinical history of infertility. On the other hand, infertile women who had not used fertility drugs experienced no increase in risk (OR 0.91, 95% CI 0.66–1.3). The above risk was higher among nulligravid women than among gravid women. Nevertheless, the information available on specific fertility medication was too incomplete to draw any conclusions.

A case-control study found that women taking clomiphene had a higher risk of developing the disease compared with women who were not taking clomiphene (RR 2.3, 95% CI 0.5–11.4). Prolonged use of clomiphene (12 months or more) was associated with a higher risk of ovarian cancer (RR 11.1, 95% CI 1.5–82.3). Nonetheless, treatment with the drug for less than 1 year was not associated with increased risk (Rossing et al 1994).

On the other hand, several reviews have reported insufficient evidence to support a direct causal relationship between fertility drug treatment and ovarian cancer (Nugent et al 1998, Klip et al 2000).

A UK epidemiological report of cancer incidence among women who had ovarian stimulation treatment found no evidence of a link between infertility treatment and ovarian cancer. This cohort study included 5556 women of whom 75% received ovulation induction drug treatment. The incidence rates of ovarian carcinoma were not significantly different from expectation based on national cancer rates (Doyle et al 2002).

It is acknowledged that nulliparous women who have not received any fertility treatment have almost double the risk of ovarian malignancy. Therefore, the association between nulliparity, infertility and ovarian cancer needs to be considered, as infertility appears to be an independent risk factor for ovarian malignancy. This link may be the reason behind the conflicting results of research.

In view of the above controversial evidence, women who receive ovulation induction therapy should be monitored closely and the number of treatment cycles should be shortened. It is accepted that ovulation induction with

clomiphene is not associated with increased risk of ovarian malignancy, provided it is not used for more than 12 cycles. Its administration should be confined to the lowest effective dose. Gonadotrophins should be used for the lowest number of cycles and at the lowest effective doses possible.

Women who undergo fertility treatment ought to be counselled regarding the possible association between medical ovulation induction and ovarian cancer, and their informed consent should be sought (National Institute for Health and Clinical Excellence 2004). A survey of women attending a fertility clinic reported that the majority (67%) of women were aware of the potential link between fertility treatment and ovarian cancer. Moreover, 79% of participants were willing to accept this potential increased risk (Rosen et al 1997).

Other cancers

There is no current evidence to support a link between ovulation induction therapy and other cancers, such as breast, cervical, endometrial, colorectal and thyroid cancer and melanoma (Klip et al 2000).

Prion disease

It is common knowledge that products derived from or containing materials of human or bovine origin carry the theoretical risk of transmitting prion disease. This risk could apply to gonadotrophins of pituitary or urinary extraction origin. Nevertheless, to date, there has been no evidence of transmission of prion disease by any gonadotrophin (National Institute for Health and Clinical Excellence 2004). As a precaution, the Committee on Safety of Medicines recommended that no human urine used in the production of medicines should be sourced from a country with one or more indigenous cases of variant Creutzfeldt–Jakob disease.

Conclusions

Successful induction of ovulation can usually be achieved in the majority of women with anovulation, and high pregnancy rates can be obtained provided that no other fertility factors are present. Appropriate initial investigation will determine the underlying cause and direct the clinician to the most appropriate treatment to correct anovulation.

KEY POINTS

1. The cohort of growing follicles undergoes a process of recruitment, selection, dominance and growth which takes approximately 85 days.
2. Understanding the concept of the FSH threshold and window is essential to achieve the goal of ovulation induction (i.e. development of a single follicle and subsequent ovulation in anovulatory women).
3. In developed countries, 20–25% of patients who present with infertility suffer from ovulation disorders.
4. Appropriate investigation of the hypothalamic–pituitary–ovarian axis, thyroid and adrenal function are necessary to categorize patients accurately and choose an appropriate method of ovulation induction.
5. Anovulatory patients should be fully informed of the success of each method, the monitoring required and the possible associated risks prior to initiating the treatment. Simple treatment associated with low complication rates and lower costs should be tried first.
6. Each unit offering ovulation induction treatment should be equipped with skilful ultrasonography and specialist endocrine laboratory services. Local protocols should be available to reduce or prevent the risk of multiple pregnancy and OHSS.
7. Pulsatile GnRH treatment should be the treatment of choice for anovulatory patients suffering from hypogonadotrophic hypogonadism with low levels of endogenous oestradiol because of reduced risks compared with gonadotrophin treatment.
8. Careful monitoring of ovarian response with ultrasound and serum oestradiol measurements is required in every patient administered gonadotrophin therapy.
9. Treatment of patients with PCOS with anovulation remains a challenge. If they are overweight (BMI ≥ 30), weight loss should be the first approach.
10. Laparoscopic drilling in clomiphene-resistant PCOS patients should be considered before administering gonadotrophins to avoid the risk of OHSS and multiple pregnancies.
11. The place of metformin and letrozole alone to induce ovulation in patients with PCOS is yet to be clarified from appropriate randomized controlled trials.
12. Risk factors for OHSS have been identified. If patients fall within these categories, very careful and prudent administration of gonadotrophins is required, particularly when more than one risk factor exists.
13. Cancellation of the cycle or conversion to an IVF cycle is recommended if too many follicles are recruited and reach maturity during ovulation induction cycles.
14. The association between ovarian cancer risk and gonadotrophin-stimulated cycles or prolonged clomiphene use remains unclear. The use of the lowest dose of either group of drugs which achieves ovulation is recommended.

Introduction

Polycystic ovary syndrome (PCOS) is the most common endocrine disturbance affecting women, and is a heterogeneous collection of signs and symptoms that, gathered together, form a spectrum of a disorder with a mild presentation in some women, and a severe disturbance of reproductive, endocrine and metabolic function in other women (Balen et al 1995). The pathophysiology of PCOS appears to be multifactorial. The definition of PCOS has been much debated. Key features include menstrual cycle disturbance, hyperandrogenism and obesity. There are many extraovarian aspects to the pathophysiology of PCOS, yet ovarian dysfunction is central. The international consensus definition of PCOS is the presence of two out of the following three criteria: (i) oligo-ovulation and/or anovulation; (ii) hyperandrogenism (clinical and/or biochemical); and (iii) polycystic ovaries, with the exclusion of other aetiologies of menstrual disturbance or hyperandrogenism (Fauser et al 2004). There is considerable heterogeneity of symptoms and signs amongst women with PCOS, and for an individual, these may change over time. Polycystic ovaries can exist without clinical signs of PCOS, expression of which may be precipitated by various factors, most predominantly an increase in body weight.

The morphology of the polycystic ovary is an ovary with 12 or more follicles measuring 2–9 mm in diameter and/or increased ovarian volume ($>10\text{ cm}^3$) (Balen et al 2003) (Figures 18.1–18.5). Polycystic ovaries are commonly detected by pelvic ultrasound, with estimates of prevalence in the general population being in the order of 20–33% (Michelmores et al 1999). However, not all women with polycystic ovaries demonstrate the clinical and biochemical features which define PCOS. These include menstrual cycle disturbances, hirsutism, acne, alopecia and abnormalities of biochemical profiles, including elevated serum concentra-

tions of luteinizing hormone (LH), testosterone and androstenedione. Obesity and hyperinsulinaemia are associated features, although only 40–50% of women with PCOS are overweight (Balen and Michelmores 2002). Presentation of PCOS is so varied that one, all or any combination of the above features may be present in association with an ultrasound picture of polycystic ovaries (Table 18.1).

Pathogenesis

The pathogenesis of polycystic ovaries and PCOS is still being elucidated, but the heterogeneity of presentation of PCOS suggests that a single cause is unlikely. Some genetic studies have identified a link between PCOS and disordered insulin metabolism, and indicate that PCOS may be the presentation of a complex genetic trait disorder (Franks et al 2001). PCOS runs in families, with approximately half of first-degree relatives (i.e. sisters, mothers and daughters) also being affected; incidentally, male relatives also show an increased rate of metabolic problems. The features of obesity, hyperinsulinaemia and hyperandrogenaemia, which are commonly seen in PCOS, are also known to be factors which confer an increased risk of cardiovascular disease and type 2 diabetes (Rajkowska et al 2000). There are studies which indicate that women with PCOS have an increased risk for these diseases which pose long-term risks for health.

PCOS appears to have its origins during adolescence and is thought to be associated with increased weight gain during puberty. However, the polycystic ovary gene(s) has not yet been identified, and the effects of environmental influences such as weight changes and circulating hormone concentrations, and the age at which these occur, are still being unravelled. Prior to puberty, there appears to be two periods of increased ovarian growth. The first is at adrenarche in response to increased concentrations of circulating

Table 18.1 The spectrum of clinical manifestations of polycystic ovary syndrome

Symptoms	Serum endocrinology	Possible late sequelae
Obesity	↑ Androgens (testosterone and androstenedione)	Diabetes mellitus Dyslipidaemia
Menstrual disturbance	↑ Luteinizing hormone	Hypertension
Infertility	↑ Fasting insulin ↑ Prolactin	Cardiovascular disease
Hyperandrogenism	↓ Sex-hormone-binding globulin ↑ Oestradiol, oestrone	Endometrial carcinoma Breast cancer
Asymptomatic

androgens, and the second is just before and during puberty due to rising gonadotrophin levels, and the actions of growth hormone, insulin-like growth factor-1 (IGF-1) and insulin on the ovary. Sampaolo et al (1994) reported a study of 49 obese girls at different stages of puberty, com-

paring their pelvic ultrasound features and endocrine profiles with 35 age- and pubertal-stage-matched controls. They found that obesity was associated with a significant increase in uterine and ovarian volume. They also found that obese postmenarcheal girls with polycystic ovaries had larger

uterine and ovarian volumes than obese postmenarcheal girls with normal ovaries. Sampaolo et al concluded that obesity leads to hyperinsulinism, which causes both hyperandrogenaemia and raised IGF-1 levels, which augments the ovarian response to gonadotrophins. This implies that obesity may be important in the pathogenesis of polycystic ovaries, but further study is required to evaluate this. It is known that obesity is not a prerequisite for PCOS. After menarche, it is common for the menstrual cycle to be erratic for several months. If the irregularity persists beyond 2 years, there is a high chance that the adolescent girl has PCOS.

Investigations

The investigation of PCOS requires the exclusion of specific underlying diseases of the hypothalamic–pituitary–ovarian axis and the adrenal glands in order to exclude endocrine causes of menstrual cycle disturbance (e.g. hyperprolactinaemia, thyroid disease, hypothalamic dysfunction, ovarian

failure), and other causes of androgen excess such as congenital adrenal hyperplasia (CAH), Cushing's syndrome or androgen-secreting tumours of the ovary or adrenal gland.

Endocrine profile

An endocrine profile is best taken during a menstrual bleed, although it may need to be taken at random in an oligomenorrhoeic or amenorrhoeic woman. Follicle-stimulating hormone (FSH), LH, oestradiol, testosterone, prolactin and thyroid function should be measured. If the patient wishes to conceive, it is necessary to ascertain whether ovulation is occurring. Patients with anovulatory infertility will have oligomenorrhoea or amenorrhoea and a low luteal-phase progesterone. A progesterone concentration of more than 30 nmol/l suggests ovulation, but it can be difficult to know when to take the blood if the patient has an erratic cycle, and impossible if she is amenorrhoeic. If the progesterone concentration is 15–30 nmol/l, the timing may have been incorrect. It is then necessary to check the timing of the blood test to subsequent menstruation, and repeat the test

Table 18.2 Hormonal patterns in different causes of menstrual irregularity

Follicle-stimulating hormone	Luteinizing hormone	Oestradiol	Diagnosis
Normal	Elevated	Usually normal	Polycystic ovary syndrome
Normal	Low	Low	Weight-related amenorrhoea
Low	Low	Low	Hypogonadotrophic hypogonadism, functional or organic
Elevated	Elevated	Low	If oligomenorrhoeic or amenorrhoeic: ovarian failure
Elevated	Elevated	High	If mid-cycle, think of mid-cycle surge

in the following cycle (sometimes two progesterone measurements in the same cycle are helpful). The optimal way to assess ovulation in women with irregular cycles is by a combination of serial ultrasound scans and serum endocrine measurements (FSH and LH in the follicular phase, progesterone in the luteal phase).

Women with PCOS usually have a normal serum FSH concentration (Table 18.2). LH is the second gonadotrophin which, like FSH, is released by the gonadotrophs in the anterior pituitary gland, under the influence of pulsatile release of gonadotrophin-releasing hormone (GnRH). The differential control of FSH and LH secretion relies upon the need for priming of the pituitary by oestradiol before it will become responsive to GnRH and release LH. FSH secretion, on the other hand, is under tonic inhibitory control by inhibin acting in a negative feedback loop from the ovaries. Therefore, in times of oestrogen deficiency, such as weight-related amenorrhoea, LH concentrations in the circulation are lower than FSH, whilst the mid-cycle surge that is primed by rising oestradiol secretion from the ovary results in a greater release of LH than FSH.

An elevated serum concentration of LH in the follicular phase of the cycle suggests that the patient has PCOS, usually associated with a concentration of more than 10 IU/l in the early to mid-follicular phase of the cycle. In a series of over 1700 women with PCOS, approximately 40% of patients were found to have an elevated serum concentration of LH, which was associated with a significantly higher risk of infertility than in those with normal LH levels (Balen et al 1995). Other causes of an elevated LH serum concentration are the mid-cycle surge and ovarian failure (Table 18.2).

LH stimulates ovarian production of androgens, and LH is most commonly elevated in slim women with PCOS. In overweight women, hypersecretion of insulin is the main cause of androgen secretion by the ovaries.

The normal female range for total serum testosterone is 0.5–3.5 nmol/l. The most usual cause of an elevated serum testosterone level is PCOS. Most women with PCOS, however, have a normal total serum testosterone concentration. Measurement of the sex-hormone-binding globulin (SHBG) concentration (normal range 16–119 nmol/l) will permit calculation of the 'free androgen index' [(testosterone \times 100)/SHBG], which should be less than 5. Women who are obese have high circulating levels of insulin which reduces synthesis of SHBG by the liver, so the free androgen index is often elevated when total testosterone is in the normal range.

If the serum testosterone concentration is greater than 5 nmol/l, it is necessary to exclude other causes of hyperandrogenaemia, such as late-onset CAH, Cushing's syndrome and androgen-secreting tumours. Women with the most common form of CAH (21-hydroxylase deficiency) will have an elevated serum 17-hydroxyprogesterone concentration (17-OHP >20 nmol/l) and an exaggerated response to an intravenous bolus of adrenocorticotrophic hormone (250 mg tetracosactrin will cause an elevation of 17-OHP, usually between 65 and 470 nmol/l).

Features of hyperandrogenism

Signs of hyperandrogenism (acne, hirsutism, balding) are suggestive of PCOS, although biochemical screening helps to differentiate other causes of androgen excess. Hirsutism can be graded and given a 'Ferriman Gallwey score'. It is useful to monitor the progress of hirsutism, or its response to treatment, by making serial records, either using a chart or by taking photographs of affected areas of the body. It is important to distinguish between hyperandrogenism and virilization, which is associated with high circulating androgen levels and causes deepening of the voice, increase in muscle bulk, breast atrophy and cliteromegaly. Virilization suggests a more profound disturbance of androgen secretion than usually seen with PCOS, and indicates the need to exclude CAH, Cushing's syndrome and androgen-secreting tumours.

Hyperinsulinaemia

The association between insulin resistance, compensatory hyperinsulinaemia and hyperandrogenism has provided insight into the pathogenesis of PCOS. The cellular and molecular mechanisms of insulin resistance in PCOS have been investigated extensively, and it is evident that the major defect is a decrease in insulin sensitivity secondary to a post-binding abnormality in insulin-receptor-mediated signal transduction, with a less substantial, but significant, decrease in insulin responsiveness (Dunaif 1997). It appears that decreased insulin sensitivity in PCOS is potentially an intrinsic defect in genetically susceptible women, since it is independent of obesity, metabolic abnormalities, body fat topography and sex hormone levels.

Although the insulin resistance may occur irrespective of body mass index (BMI), the common association between PCOS and obesity has a synergistic deleterious impact on glucose homeostasis, and can worsen both hyperandrogen-

ism and anovulation. An assessment of BMI alone is not thought to provide a reliable prediction of cardiovascular risk. It has been reported that the association between BMI and coronary heart disease almost disappeared after correction for dyslipidaemia, hyperglycaemia and hypertension. Some women have profound metabolic abnormalities in the presence of a normal BMI, and others have few risk factors with an elevated BMI. It has been suggested that rather than BMI itself, it is the distribution of fat that is important, with android obesity being more of a risk factor than gynaecoid obesity. Hence the value of measuring the waist:hip ratio or waist circumference, which detect abdominal visceral fat rather than subcutaneous fat. It is the visceral fat which is metabolically active and, when increased, results in increased rates of insulin resistance, type 2 diabetes, dyslipidaemia, hypertension and left ventricular enlargement. There is a closer link between waist circumference and visceral fat mass, as assessed by computer tomography, than waist:hip ratio or BMI (Lord and Wilkin 2002). Waist circumference should ideally be less than 79 cm, whilst a measurement of greater than 87 cm carries a significant risk. Exercise has a significant effect on reducing visceral fat and reducing cardiovascular risk; indeed, a 10% reduction in body weight may equate to a 30% reduction in visceral fat.

Insulin acts through multiple sites to increase endogenous androgen levels. Increased peripheral insulin resistance results in a higher serum insulin concentration. Excess insulin binds to IGF-1 receptors which enhances androgen production by theca cells in response to LH stimulation. Hyperinsulinaemia also decreases the synthesis of SHBG by the liver. Therefore, there is an increase in the serum free testosterone concentration, and consequent peripheral androgen action. Intraovarian androgen excess is responsible for anovulation by acting directly on the ovary, promoting the process of follicular atresia. This latter process is characterized by apoptosis of granulosa cells. As a consequence, there is an increasingly larger stromal compartment, which retains LH responsiveness and continues to secrete androgens. Hyperinsulinaemia also stimulates trophic changes in the skin that results in acanthosis nigricans in the skin creases (Figure 18.6).

Insulin resistance is defined as a reduced glucose response to a given amount of insulin and may occur secondary to resistance at the insulin receptor, decreased hepatic clearance of insulin and/or increased pancreatic sensitivity. Both obese and non-obese women with PCOS are more insulin resistant and hyperinsulinaemic than age- and weight-matched women with normal ovaries. Thus, there appear to be factors in women with PCOS which promote insulin resistance and that are independent of obesity.

Insulin resistance can be measured by a number of expensive and complex tests, but it is not necessary to measure it routinely in clinical practice; it is more important to check for impaired glucose tolerance. Simple screening tests for risk of impaired glucose tolerance (IGT) include an assessment of BMI and waist circumference. If the fasting blood glucose is less than 5.2 mmol/l, the risk of impaired glucose tolerance is low. The 2-h standard 75 g oral glucose tolerance test may be conducted in those at high risk (BMI >30 kg/m² in Caucasian women and >25 kg/m² in women from South Asia, who have a greater degree of insulin resistance at a lower body weight) (Table 18.3).

Heterogeneity of PCOS

A few years ago, the author reported a large series of women with polycystic ovaries detected by ultrasound scan

Figure 18.6 Acanthosis nigricans as seen typically in the axilla or skin of the neck in women with insulin resistance. (A) Axilla. (B) Close-up, demonstrating hypertrophic and pigmented skin.

Table 18.3 Definitions of glucose tolerance after a 75 g glucose tolerance test

	Diabetes mellitus	Impaired glucose tolerance	Impaired fasting glycaemia
Fasting glucose (mmol/l)	≥7.0	<7.0	≥6.1 and <7.0
2-h glucose (mmol/l)	≥11.1	≥7.8	<7.8
Action	Refer to diabetic clinic	Dietary advice. Check fasting glucose annually	Dietary advice. Check fasting glucose annually

(Balen et al 1995). All of the 1871 patients had at least one symptom of PCOS. Thirty-eight percent of the women were overweight (BMI >25 kg/m²). Obesity was significantly associated with an increased risk of hirsutism, menstrual cycle disturbance and an elevated serum testosterone concentration. Obesity was also associated with an increased rate of infertility. Twenty-six percent of patients with primary infertility and 14% of patients with secondary infertility had a BMI of more than 30 kg/m². Approximately 30% of the patients had a regular menstrual cycle, 50% had oligomenorrhoea and 20% had amenorrhoea. In this study, the classical endocrine features of raised serum LH and testosterone were found in 40% and 30% of patients, respectively. Ovarian volume was significantly correlated with serum LH and testosterone concentrations. Other studies have reported correlation between markers of insulin resistance and ovarian volume and ovarian stromal echogenicity, which in turn have been correlated with androgen production.

National and racial differences in expression

Approximately 75–80% of women with polycystic ovaries have signs or symptoms of PCOS. Thus, in the UK, where it has been reported that up to 33% of women have polycystic ovaries (Michelmores et al 1999), 20–25% of women may have a degree of PCOS, albeit mild in many cases. There are large national and ethnic variations in the expression of PCOS, with women from the Far East having little in the way of hirsutism, whilst those with dark hair from Mediterranean and Middle Eastern or South Asian countries have a greater degree of expression. The highest reported prevalence of polycystic ovaries has been 52% among South Asian immigrants in Britain, of whom 49% had menstrual irregularity (Rodin et al 1998). It was also shown that South Asian women with polycystic ovaries had a comparable degree of insulin resistance to controls with established type 2 diabetes. Generally, there has been a paucity of data of the prevalence of PCOS among women of South Asian origin, both among migrant and native groups. Type 2 diabetes and insulin resistance have a high prevalence among indigenous populations in South Asia, with a rising prevalence among women. Insulin resistance and hyperinsulinaemia are common antecedents of type 2 diabetes, with a high prevalence in South Asians. Type 2 diabetes also has a familial basis, inherited as a complex genetic trait that interacts with environmental factors, chiefly nutrition, commencing from fetal life. It has been shown that ethnic variations in the overt features of PCOS (symptoms of hyperandrogenism, menstrual irregularity and obesity) in women of South Asian descent are linked to the higher prevalence and degree of insulin resistance in South Asians. It has also been shown that South Asians with anovulatory PCOS have greater insulin resistance and more severe symptoms of PCOS than anovular White Caucasians with PCOS (Wijayaratne et al 2002).

The question remains as to whether differences in expression of PCOS are due to dietary and lifestyle factors or to genetic variations in hormone actions, such as polymorphisms in gonadotrophin subunits or receptor function (affecting the expression of androgens, gonadotrophins or insulin). A full discussion of the genetics of PCOS is beyond the scope of this chapter, and there are a number of candi-

date genes that have been proposed (see Franks et al 2001). It may be that some families or racial groups have genetic differences that affect the expression or presentation of PCOS.

Health Consequences

Ischaemic heart disease

Obesity and metabolic abnormalities are recognized risk factors for the development of ischaemic heart disease (IHD) in the general population, and these are also recognized features of PCOS. In Europe, IHD accounts for 18% of deaths in men and 14% of deaths in women. In men, the incidence of IHD increases after the age of 35 years, while in women, an increased incidence is noted after the age of 55 years. The questions are whether women with PCOS are at increased risk of IHD, and whether this will occur at an earlier age than in women with normal ovaries. The basis for the idea that women with PCOS are at greater risk for cardiovascular disease is that these women are more insulin resistant than weight-matched controls, and that the metabolic disturbances associated with insulin resistance are known to increase cardiovascular risk in other populations.

Insulin resistance

In the general population, cardiovascular risk factors include insulin resistance, obesity (especially an increase in waist circumference), glucose intolerance, diabetes, hypertension and dyslipidaemia (particularly raised serum triglycerides). Insulin sensitivity varies depending upon menstrual pattern. Women with PCOS who are oligomenorrhoeic are more likely to be insulin resistant than those with regular cycles, irrespective of their BMI. Women with PCOS have a defect in insulin signalling at the insulin receptor, which causes insulin resistance. The sex-steroid-induced increase in growth hormone that initiates the adolescent growth spurt also leads to insulin resistance, and explains the timing of onset of symptoms in those prone to develop PCOS. The presence of obesity and/or type 2 diabetes worsens the degree of insulin resistance.

Insulin resistance is restricted to the extrasplanchnic actions of insulin on glucose dispersal. The liver is not affected [hence the decrease in SHBG and high-density lipoproteins (HDLs)], and neither is the ovary (hence the menstrual problems and hypersecretion of androgens) nor the skin (hence the development of acanthosis nigricans). Insulin resistance causes compensatory hypersecretion of insulin, particularly in response to glucose, so euglycaemia is usually maintained at the expense of hyperinsulinaemia.

It is reported that up to 20% of slim women and 40% of obese women with PCOS demonstrate impaired glucose tolerance. Insulin resistance combined with abdominal obesity is thought to account for the higher prevalence of type 2 diabetes in PCOS. There is a concomitant increased risk of gestational diabetes.

Dyslipidaemic women with PCOS have high concentrations of serum triglycerides and suppressed HDL levels, particularly a lower HDL₂ subfraction. HDLs play an important role in lipid metabolism and are the most important lipid parameter in predicting cardiovascular risk in women. HDLs

perform the task of 'reverse cholesterol transport'. That is, they remove excess lipids from the circulation and tissues to transport them to the liver for excretion, or transfer them to other lipoprotein particles.

In a large retrospective study, Pierpoint et al (1998) reported the mortality rate in 1028 women diagnosed with PCOS between 1930 and 1979. All of the women were over 45 years of age and 770 women had been treated by wedge resection of the ovaries. In total, 786 women were traced; the mean age at diagnosis was 26.4 years and the average duration of follow-up was 30 years. There were 59 deaths, of which 15 were from circulatory disease. Of these 15 deaths, 13 were from IHD. There were six deaths from diabetes as an underlying or contributory cause, compared with the expected 1.7 deaths. The standardized mortality rate (SMR), both overall and for cardiovascular disease, was not higher in the women with PCOS compared with the national mortality rates in women, although the observed proportion of women with diabetes as a contributory or underlying factor leading to death was significantly higher than expected [odds ratio 3.6, 95% confidence interval (CI) 1.5–8.4]. Thus, despite surrogate markers for cardiovascular disease, Pierpoint et al (1998) found no increased rate of death from cardiovascular disease. A follow-up report from the same study, however, did demonstrate an increased, although non-significant, risk of death due to diabetes [after adjustment for BMI, the odds ratio was 2.2 (95% CI 0.9–5.2) for diabetes (Wild et al 2000)]. There was still no increase in long-term coronary heart disease mortality in the PCOS group, although there was evidence of increased stroke-related mortality, even after adjustment for BMI.

Homocysteine

A moderately increased total plasma homocysteine (Hcy) concentration is associated with an increased risk of atherosclerosis. Hcy is an essential intermediate in the transfer of activated methyl groups from tetrahydrofolate to S-adenosylmethionine, in the synthesis of cysteine from methionine, and in the production of homocysteine thiolactone. An abnormal elevation of Hcy in plasma and urine is caused by an imbalance between Hcy production and metabolism, which can be of demographic, genetic, nutritional or metabolic aetiology, and is associated with premature vascular disease. Mild hyperhomocysteinaemia has been demonstrated to induce sustained injury to the arterial endothelial cells that accelerate the development of thrombosis and atherosclerosis. Normal concentrations of total plasma Hcy are in the range of 5–16 $\mu\text{mol/l}$, although 10 $\mu\text{mol/l}$ is considered to be the desirable upper limit; there is an age-related rise and lower concentrations are found in women. There have been reports of elevated plasma Hcy in Caucasian women with PCOS, and this may be greater in the South Asian population (Rendeva et al 2002). Weight reduction and regular physical exercise are recognized interventions that help to reduce insulin resistance and the metabolic syndrome.

Endometrial cancer

Endometrial adenocarcinoma is the second most common female genital malignancy, but only 4% of cases occur in

women under 40 years of age. The risk of developing endometrial cancer has been shown to be adversely influenced by a number of factors including obesity, long-term use of unopposed oestrogens, nulliparity and infertility. The relative risk of endometrial cancer is 1.6 in women with a menarche before the age of 12 years, and 2.4 in women who have their menopause after the age of 52 years (Elwood et al 1977). Women with endometrial carcinoma have had fewer births compared with controls, and it has also been demonstrated that infertility per se gives a relative risk of 2. Hypertension and type 2 diabetes have long been linked to endometrial cancer, with relative risks of 2.1 and 2.8, respectively; these conditions are now known to be associated with PCOS.

A study by Coulam et al (1983) examined the risk of developing endometrial carcinoma in a group of 1270 patients who were diagnosed with chronic anovulation syndrome. The defining characteristics of this group included pathological or macroscopic evidence of the Stein–Leventhal syndrome, or a clinical diagnosis of chronic anovulation. This study identified the excess risk of endometrial cancer to be 3.1 (95% CI 1.1–7.3), and proposed that this might be due to abnormal levels of unopposed oestrogen. However, the true risk of endometrial carcinoma in women with PCOS is difficult to ascertain.

Endometrial hyperplasia

Endometrial hyperplasia may be a precursor to adenocarcinoma, with cystic glandular hyperplasia progressing in perhaps 0.4% of cases and adenomatous hyperplasia in up to 18% of cases over 2–10 years. Precise estimation of the rate of progression is impossible to determine. Some authors have reported conservative management of endometrial adenocarcinoma in women with PCOS, with a combination of curettage and high-dose progestogens. The rationale is that cancer of the endometrium often presents at an early stage, is well differentiated, has a low risk of metastasis, and therefore is not perceived as being life threatening, while poorly differentiated adenocarcinoma in a young woman has a worse prognosis and warrants hysterectomy. In general, however, the literature on women with PCOS and endometrial hyperplasia or adenocarcinoma suggests that this group has a poor prognosis for fertility. This may be because of the factors that predispose to the endometrial pathology — chronic anovulation often combined with severe obesity — or secondary to the endometrial pathology disrupting potential embryonic implantation. Thus, a more traditional and radical surgical approach (i.e. hysterectomy) is suggested as the safest way to prevent progression of the cancer (Balen 2001).

Although the degree of risk has not been clearly defined, it is generally accepted that for women with PCOS who experience amenorrhoea or oligomenorrhoea, the induction of artificial withdrawal bleeds to prevent endometrial hyperplasia is prudent management. Indeed, the author considers it important that women with PCOS should shed their endometrium at least every 3 months. For those women with oligomenorrhoea or amenorrhoea who do not wish to use cyclical hormone therapy, an ultrasound scan is recommended to measure endometrial thickness and morphology every 6–12 months (depending upon menstrual history). An

endometrial thickness of more than 10 mm in an amenorrhoeic woman warrants an artificially induced bleed, which should be followed by a repeat ultrasound scan and endometrial biopsy if the endometrium has not been shed. Another option is to consider a progestogen-secreting intrauterine system, such as the Mirena.

Breast cancer

Obesity, hyperandrogenism and infertility occur frequently in PCOS, and are features known to be associated with the development of breast cancer. However, studies examining the relationship between PCOS and breast carcinoma have not always identified a significantly increased risk. The study by Coulam et al (1983) calculated a relative risk of 1.5 (95% CI 0.75–2.55) for breast cancer in their group of women with chronic anovulation, which was not statistically significant. After stratification by age, however, the relative risk was found to be 3.6 (95% CI 1.2–8.3) in the postmenopausal age group. More recently, Pierpoint et al (1998) reported SMRs calculated for patients with PCOS compared with the normal population. The SMR for all neoplasms was 0.91 (95% CI 0.60–1.32) and the SMR for breast cancer was 1.48 (95% CI 0.79–2.54). In fact, breast cancer was the leading cause of death in this cohort.

Ovarian cancer

In recent years, there has been much debate about the risk of ovarian cancer in women with infertility, particularly in relation to the use of drugs to induce superovulation for assisted conception procedures. Inherently, the risk of ovarian cancer appears to be increased in women who have multiple ovulations; that is, those who are nulliparous (possibly because of infertility) with an early menarche and late menopause. Thus, it may be that inducing multiple ovulations in women with infertility will increase their risk; a hypothesis that is by no means proven. Women with PCOS who are oligo-ovulatory or anovulatory might therefore be expected to be at low risk of developing ovarian cancer if it is lifetime number of ovulations rather than pregnancies that is critical. Ovulation induction to correct anovulatory infertility aims to induce unifollicular ovulation and so, in theory, should increase the risk of a woman with PCOS compared with that of a normal ovulating woman. The polycystic ovary, however, is notoriously sensitive to stimulation and it is only in recent years, with the development of high-resolution transvaginal ultrasonography, that the rate of unifollicular ovulation has attained acceptable levels. The use of clomiphene citrate and gonadotrophin therapy for ovulation induction in the 1960s, 1970s and 1980s resulted in many more multiple ovulations (and indeed multiple pregnancies) than in recent times, and might therefore present with an increased rate of ovarian cancer when these women reach their 60s, the age of greatest incidence.

A few studies have addressed the possibility of an association between polycystic ovaries and ovarian cancer. The results are conflicting, and generalizability is limited due to problems with the study designs. In the large UK study of Pierpoint et al (1998), the SMR for ovarian cancer was 0.39 (95% CI 0.01–2.17).

Management of Non-Fertility Aspects of Polycystic Ovaries

Psychological support and quality of life

The symptoms typically associated with the condition have also been shown to lead to a significant reduction in health-related quality of life (Jones et al 2004). Health-related quality of life is a multidimensional, dynamic concept that encompasses physical, psychological and social aspects that are associated with a particular disease or its treatment. Therefore, any management of the woman with PCOS needs to consider and understand the negative impact that this condition may have upon these psychosocial parameters. For example, although the management of hirsutism may be considered as a purely cosmetic issue, excessive facial hair has been shown to be one of the major causes of marked psychological stress in women with PCOS, often caused by embarrassment about the excessive hair growth. Infertility and weight issues have also been found to affect other social and psychological parameters. Infertility can cause tensions within the family, altered self-perception and problems at work. Whilst obesity worsens the symptoms, the metabolic scenario conspires against weight loss; many women experience frustration in attempts to lose weight and suffer from low-esteem and poor body image.

Obesity

The management of women with PCOS should be focused on the patient's particular problems. Obesity worsens both symptomatology and the endocrine profile, so obese women (BMI >30 kg/m²) should be encouraged to lose weight by a combination of calorie restriction and exercise. Weight loss improves the endocrine profile, the likelihood of ovulation and the likelihood of a healthy pregnancy.

Metformin

Insulin-sensitizing agents such as metformin became popular for the management of PCOS as it was thought that they might act directly at the pathogenesis of the syndrome and help to correct both metabolic and endocrine problems. Early studies suggested an improvement in reproductive function and menstrual cycle regulation, and the possibility of benefits to health of long-term use, including deferring the onset of type 2 diabetes. However, the results of large prospective, randomized studies have failed to demonstrate benefit; weight loss is not achieved by the therapy, and whilst some biochemical parameters may improve, this does not translate into a significant benefit in outcomes. Therefore, at present, the role of insulin-sensitizing and insulin-lowering drugs, such as metformin and the thiazolidinediones, is uncertain in the management of PCOS.

Diet

Much has been written about diet and PCOS. The right diet for an individual is one that is practical, sustainable and compatible with her lifestyle. There does not appear to be a particular diet that is most appropriate for women with

PCOS. It is sensible to reduce glycaemic load by lowering sugar content in favour of more complex carbohydrates, and to avoid fatty foods. Meal replacement therapy or low calorie diets may be appropriate; it is often helpful to refer to a dietitian, if available. An increase in physical activity is essential, preferably as part of the daily routine. Thirty minutes of brisk exercise per day is encouraged to maintain health; but to lose weight, or sustain weight loss, 60–90 min/day is advised. Concurrent behavioural therapy improves the chances of success of any method of weight loss.

Antiobesity drugs

These may help with weight loss, and both orlistat and sibutramine have been shown to be effective in PCOS in small studies. Orlistat is a pancreatic lipase inhibitor which prevents absorption of approximately 30% of dietary fat, whereas sibutramine is a centrally acting serotonin and noradrenaline reuptake inhibitor which enhances satiety. Both agents can also improve insulin sensitivity and are currently licensed for individuals with a BMI of more than 30 kg/m², or lower if comorbidities such as type 2 diabetes are present. Both agents have been shown to improve insulin resistance, lipid profile and glycaemic control, and orlistat has been shown to reduce blood pressure and testosterone. Orlistat and sibutramine are increasingly being used in primary care as an adjunct to diet and lifestyle advice; both require monitoring for efficacy, and sibutramine requires monitoring for possible increases in blood pressure. New agents in development for obesity may also have a role to play in PCOS.

Bariatric surgery

This is being used increasingly because of the global epidemic of obesity, and it certainly has a role in the management of obese women with PCOS. It is recommended by some that anyone with a BMI of more than 35 kg/m² should be referred for consideration of bariatric surgery. If there are comorbidities, such as diabetes, the BMI cut-off for surgery is less than 30–35 kg/m².

Menstrual irregularity

The simplest way to control the menstrual cycle is the use of a low-dose combined oral contraceptive preparation (COCP). This will result in an artificial cycle and regular shedding of the endometrium. It is also important, once again, to encourage weight loss. As women with PCOS are thought to be at increased risk of cardiovascular disease, a 'lipid friendly' combined contraceptive pill should be used. The third-generation oral contraceptives are lipid friendly but present the potential disadvantage of venous thromboembolism, particularly in overweight women. Dianette® is a COCP that has antiandrogenic properties and will have additional benefits for women with hyperandrogenism, and Yasmin® contains a newer antiandrogen, drospirenone, which is a derivative of spironolactone. Alternatives to the COCP include a progestogen, for example medroxyprogesterone acetate (Provera) or dydrogesterone (Duphaston), for 12 days every 1–3 months to induce a withdrawal bleed, or simply the insertion of a Mirena intrauterine system.

In women with anovulatory cycles, the action of oestradiol on the endometrium is unopposed because of the lack of

cyclical progesterone secretion. This may result in episodes of irregular uterine bleeding and, in the long term, endometrial hyperplasia and even endometrial cancer (see above). An ultrasound assessment of endometrial thickness provides a bioassay for oestradiol production by the ovaries and conversion of androgens in the peripheral fat. If the endometrium is thicker than 10 mm, a withdrawal bleed should be induced; if the endometrium fails to shed, endometrial sampling is required to exclude endometrial hyperplasia or malignancy.

Hyperandrogenism and hirsutism

The bioavailability of testosterone is affected by the serum concentration of SHBG. High levels of insulin lower the production of SHBG and therefore increase the free fraction of androgen. Elevated serum androgen concentrations stimulate peripheral androgen receptors, resulting in an increase in 5- α reductase activity, directly increasing the conversion of testosterone to the more potent metabolite, dihydrotestosterone. Symptoms of hyperandrogenism include hirsutism and acne, which are both distressing conditions. Hirsutism is characterized by terminal hair growth in a male pattern of distribution, including chin, upper lip, chest, upper and lower back, upper and lower abdomen, upper arm, thigh and buttocks. A standardized scoring system, such as the modified Ferriman and Gallwey score, should be used to evaluate the degree of hirsutism before and during treatments (Figure 18.7).

Treatment options include cosmetic and medical therapies. As drug therapies may take 6–9 months or longer before any improvement in hirsutism is perceived, physical treatments including electrolysis, waxing and bleaching may be helpful whilst waiting for medical treatments to work. For many years, the most 'permanent' physical treatment for unwanted hair has been electrolysis. It is time consuming, painful and expensive, and should be performed by an expert practitioner. Regrowth is not uncommon and there is no really permanent cosmetic treatment, but the last few years have seen much development in the use of laser and photothermolysis techniques. There are many different types of laser in production and each requires evaluation of dose intensity, effectiveness and safety. The technique is promising, being faster and more effective than shaving, waxing or chemical depilation. Repeated treatments are required for a near-permanent effect because only those hair follicles in the growing phase are obliterated at each treatment. Hair growth occurs in three cycles so 6–9 months of regular treatments are typical. Patients should be appropriately selected (dark hair on fair skin is best), and warned that complete hair removal cannot be guaranteed and some scarring may occur. At present, it is not widely available and is still an expensive option.

Vaniqa (eflornithine) has recently been developed as a topical treatment for hirsutism. It works by inhibiting the enzyme ornithine decarboxylase in hair follicles, and may be a useful therapy for those who wish to avoid hormonal treatments, but may also be used in conjunction with hormonal therapy.

Medical regimens should stop further progression of hirsutism and decrease the rate of hair growth. Therapy for acne should aim to lower sebum excretion, alter follicular

Figure 18.7 Ferriman and Gallwey score. Each area is given a score from 1 to 4 (1 = mild, 2 = moderate, 3 = complete light coverage, 4 = heavy coverage).

cell desquamation, reduce propionibacteria and reduce inflammation.

If using antiandrogen therapy, adequate contraception is important in women of reproductive age as transplacental passage of antiandrogens may disturb the genital development of a male fetus.

The best pharmacological treatment of proven effectiveness is a combination of the synthetic progestogen cyproterone acetate, which is antigonadotrophic and antiandrogenic, with ethinyl oestradiol. Dianette contains ethinyl oestradiol (35 µg) in combination with cyproterone, although at a lower dose (2 mg). Dianette is licensed for moderate to severe hirsutism and severe acne. The antiandrogen effect reduces sebum excretion in 2–3 months and results in clinical improvement in acne in 4–6 months.

Oestrogens lower circulating androgens by a combination of a slight inhibition of gonadotrophin secretion and gonadotrophin-sensitive ovarian steroid production, and by an increase in hepatic production of SHBG resulting in lower free testosterone. Cyproterone acetate can rarely cause liver damage and liver function should be checked regularly

(after 6 months and then annually). There is conflicting data about a possible increased risk of thromboembolism, although there are many women who take Dianette on a long-term basis without any ill effects.

Spironolactone is a weak diuretic with antiandrogenic properties, and may be used at a daily dose of 25–100 mg in women with either hirsutism and/or acne in whom the COCP is contraindicated. Drospirenone is a derivative of spironolactone and contained in the new COCP, Yasmin, which also appears to be effective for women with PCOS. Other antiandrogens such as ketoconazole, finasteride and flutamide have been tried, but are not widely used in the UK for the treatment of hirsutism in women due to their adverse and potentially serious side-effects. Furthermore, they are no more effective than cyproterone acetate.

Topical antiacne agents can be safely and successfully combined with systemic antiandrogen therapy in an attempt to target as many aetiological factors as possible. However, these topical treatments alone have little effect on sebum production, so are not generally successful when utilized alone in acne associated with PCOS. Topical retinoids impact on the microcomedo which is the precursor to non-inflammatory and inflammatory acne lesions. They also have direct comedolytic and anti-inflammatory activity. These agents are useful adjuvant therapies in combination with antiandrogen treatments, and can be used as maintenance treatment after discontinuation of systemic therapy. Topical antimicrobials (benzoyl peroxide/antibiotics) have good anti-inflammatory activity and should help to reduce inflammatory lesions when used alongside antiandrogen treatment.

Oral isotretinoin, a hospital-only prescribed medication, is the single systemic therapy that targets the four main aetiological factors implicated in acne. However, it is currently only licensed for severe acne that has not responded to alternative therapies. A recent European Directive concerning isotretinoin has enforced a strict pregnancy prevention programme due to the high risk of teratogenicity with this drug. COCPs can be used safely alongside oral isotretinoin and are recommended by the European Directive. Although clinical clearance of acne lesions with oral isotretinoin is very likely, relapse rates post therapy are higher than average when acne is associated with PCOS.

Ovulation Induction

Ovulation induction has traditionally involved the use of clomiphene citrate and then gonadotrophin therapy or laparoscopic ovarian surgery in those who are clomiphene resistant. The principles of management of anovulatory infertility are firstly to optimize health before commencing therapy, for example weight loss for those who are overweight, and then induce regular unifollicular ovulation, while minimizing the risks of ovarian hyperstimulation syndrome (OHSS) and multiple pregnancy (see Chapter 17, Ovulation induction, for more information).

Obesity reduces fertility, and increases the risk of miscarriage, some congenital anomalies and pregnancy-related complications, e.g. pre-eclampsia, gestational diabetes, problems during delivery, and maternal and fetal mortality (Balen et al 2006). Monitoring treatment is also harder in

obese women because their ovaries are more difficult to see on ultrasound scans, thus raising the risk of missing multiple ovulation and multiple pregnancy. National guidelines in the UK for managing overweight women with PCOS advise weight loss, preferably to a BMI of less than 30 kg/m², before commencing drugs for ovarian stimulation (Balen and Anderson 2007).

Obese women (BMI >30 kg/m²) should therefore be encouraged to lose weight. Clark et al (1995) investigated the effects of a weight loss and exercise programme on women with anovulatory infertility, clomiphene resistance and a BMI of more than 30 kg/m². The emphasis of the study was a realistic exercise schedule combined with positive reinforcement of a suitable eating programme over a 6-month period. Weight loss had a significant effect on endocrine function, ovulation and subsequent pregnancy.

Clomiphene citrate

Antioestrogen therapy with clomiphene citrate or tamoxifen has traditionally been used as first-line therapy for anovulatory PCOS. A recent meta-analysis confirmed that clomiphene is effective in increasing pregnancy rates when compared with placebo as first-line therapy (fixed odds ratio 5.8, 95% CI 1.6–21.5; number needed to treat 5.9, 95% CI 3.6–16.7) (Beck et al 2005). Antioestrogen therapy is usually commenced on day 2 of the cycle and given for 5 days. If the patient has oligomenorrhoea or amenorrhoea, it is necessary to exclude pregnancy and then induce a withdrawal bleed with a short course of a progestogen, such as medroxy-progesterone acetate 5–20 mg/day for 5–10 days. The starting dose of clomiphene citrate is 50 mg/day for 5 days beginning on days 3–5 of the menstrual cycle. The dose of clomiphene citrate should only be increased if there is no response after three cycles, as of those women who will respond to 50 mg/day, only two-thirds will do so in the first cycle. Doses of 150 mg/day or more do not appear to be of benefit. If there is an over-response to 50 mg/day, as in some women with PCOS, the dose can be decreased to 25 mg/day.

Clomiphene citrate may cause an exaggeration in the hypersecretion of LH and have antioestrogenic effects on the endometrium and cervical mucus. All women who are prescribed clomiphene citrate should be carefully monitored with a combination of endocrine and ultrasonographic assessment of follicular growth and ovulation because of the risk of multiple pregnancies, which is approximately 10% (Figures 18.8 and 18.9). Clomiphene therapy should therefore be prescribed and managed by specialists in reproductive medicine.

Aromatase inhibitors

Aromatase inhibitors have been proposed as an alternative treatment to clomiphene citrate therapy, as the discrepancy between ovulation and pregnancy rates with clomiphene citrate has been attributed to its antioestrogenic action and oestrogen receptor depletion. The aromatase inhibitors suppress oestrogen production and thereby mimic the central reduction of negative feedback through which clomiphene citrate works. Letrozole, the most widely used antiaromatase for this indication, has been shown to be effective, in early trials, in inducing ovulation and pregnancy in women with

Figure 18.8 Stimulation of a single mature follicle in a polycystic ovary (transvaginal ultrasound scan).

Figure 18.9 Transvaginal ultrasound scan of an overstimulated polycystic ovary. Both ovaries are likely to have this appearance, and the treatment must be discontinued to minimize the risk of multiple pregnancy and ovarian hyperstimulation syndrome.

anovulatory PCOS. Anastrozole is a possible alternative. Evidence from larger trials is still awaited, but some encouragement may be taken from the solidity of the working hypothesis and the success of the preliminary results.

Gonadotrophins

Gonadotrophin therapy is indicated for women with anovulatory PCOS who have been treated with antioestrogens if they have failed to ovulate or if they have a response to clomiphene that is likely to reduce their chance of conception (e.g. persistent hypersecretion of LH or antioestrogenic effect on cervical mucus).

In order to prevent the risks of overstimulation and multiple pregnancy, the traditional standard step-up regimens (when 75–150 IU is increased by 75 IU every 3–5 days) have been replaced by low-dose step-up regimens. The low-dose step-up regimen employs a starting dose of 25–50 IU, which is only increased after 14 days if there is no response, and then by only half an ampoule every 7 days. Treatment cycles

using this approach can be quite long (up to 28–35 days), but the risk of multiple follicular growth is lower than with conventional step-up regimens (Tarlitzis et al 2008) (see Chapter 17, Ovulation induction, for more information).

It can be extremely difficult to predict the response to stimulation of a woman with polycystic ovaries; indeed, this is the greatest therapeutic challenge in all ovulation induction therapies. The polycystic ovary is characteristically quiescent, at least when viewed by ultrasound, before often exhibiting an explosive response to stimulation. It can be very challenging to stimulate the development of a single dominant follicle, and while attempts have been made to predict a multifollicular response by looking at mid-follicular endocrine profiles and numbers of small follicles, it is more difficult to do so prior to commencing ovarian stimulation and hence determine the required starting dose of gonadotrophin. In order to prevent the risks of OHSS and multiple pregnancy, however, the cycle should be cancelled on day 8 of stimulation if there are more than five to seven follicles ≥ 8 mm. Ovulation is triggered with a single injection of human chorionic gonadotrophin (hCG) 5000 units (i.m. or s.c.). The inclusion criterion for hCG administration should be the development of at least one follicle with a largest diameter of at least 17 mm. In order to reduce the risk of multiple pregnancy and OHSS, the exclusion criterion for hCG administration is the development of a total of three or more follicles larger than 14 mm in diameter. In overstimulated cycles, hCG is withheld and the patient is counselled about the risks and advised to refrain from sexual intercourse.

Insulin-sensitizing agents

It is logical to assume that therapy that achieves a fall in serum insulin concentrations should improve the symptoms of PCOS. The biguanide metformin inhibits the production of hepatic glucose, thereby decreasing insulin secretion, and also enhances insulin sensitivity at the cellular level. Early studies involved a small number of participants and were encouraging, whereas more recent large studies looking at the use of metformin either alone or combined with clomiphene citrate have failed to demonstrate significant benefit with respect to weight reduction, improved menstrual cycle function or livebirth rates (Moll et al 2006, Tang et al 2006, Legro et al 2007).

In summary, although the initial studies appeared promising, subsequent large randomized-controlled trials have not demonstrated the anticipated beneficial effects of metformin as a first-line therapy for treatment of the anovulatory patient with PCOS. The study authors concur that the primary aim for overweight women with PCOS is to make lifestyle changes with a combination of diet and exercise in order to lose weight and to improve ovarian function. In conclusion, the position of metformin in the management of PCOS is by no means clear and, on the basis of current evidence, it is not the first-line treatment of choice (Tarlitzis et al 2008).

Surgical ovulation induction

An alternative to gonadotrophin therapy for clomiphene-resistant PCOS is laparoscopic ovarian surgery, which has replaced the more invasive and damaging technique of

ovarian wedge resection. Laparoscopic ovarian surgery is free of the risks of multiple pregnancy and ovarian hyperstimulation, and does not require intensive ultrasound monitoring. Furthermore, ovarian diathermy appears to be as effective as routine gonadotrophin therapy in the treatment of clomiphene-insensitive PCOS. In addition, laparoscopic ovarian surgery is a useful therapy for anovulatory women with PCOS who fail to respond to clomiphene and who persistently hypersecrete LH, or who need a laparoscopic assessment of their pelvis, or who live too far away from the hospital to be able to attend for the intensive monitoring required in gonadotrophin therapy. Surgery does, of course, carry its own risks and must only be performed by fully trained laparoscopic surgeons.

Wedge resection of the ovaries resulted in significant adhesions (100% of cases) in some published series. The risk of adhesion formation is far less after laparoscopic ovarian diathermy (10–20% of cases), and the adhesions that do form are usually fine and of limited clinical significance. The author's technique involves instilling 200 ml Hartmann's solution or Adept® into the pouch of Douglas, which, by cooling the ovaries, prevents heat injury to adjacent tissues and reduces adhesion formation. It is suggested that a minimum amount of ovarian destruction should be employed. Furthermore, a combined approach may be suitable for some women, whereby low-dose diathermy is followed by low-dose ovarian stimulation.

An additional concern is the possibility of ovarian destruction leading to ovarian failure; an obvious disaster in a woman wishing to conceive. Cases of ovarian failure have been reported after both wedge resection and laparoscopic surgery. An unfortunate vogue has developed whereby women with polycystic ovaries who have over-responded to superovulation for in-vitro fertilization (IVF) are subjected to ovarian diathermy as a way of reducing the likelihood of subsequent OHSS. If one accepts that appropriately performed ovarian diathermy works by sensitizing the ovary to FSH, one could extrapolate that ovarian diathermy prior to superovulation for IVF should make the ovary more, and not less, likely to overstimulate. The amount of ovarian destruction that is required to reduce the chance of overstimulation is therefore likely to be considerable. Great caution is urged before proceeding with such an approach because of concerns about permanent ovarian atrophy.

After laparoscopic ovarian surgery, serum concentrations of LH and testosterone fall with restoration of ovarian activity. Whether or not patients respond to laparoscopic ovarian diathermy (LOD) appears to depend on their pretreatment characteristics, with patients with high basal LH concentrations having a better clinical and endocrine response. Ovarian diathermy appears to be as effective as routine gonadotrophin therapy in the treatment of clomiphene-citrate-insensitive PCOS, and the Cochrane Database concludes that whilst there is insufficient evidence to demonstrate a difference between 6–12 months follow-up after LOD and three to six cycles of ovulation induction with gonadotrophins, multiple pregnancy rates are considerably reduced with LOD (Farquhar et al 2002). The largest randomized controlled trial to date is a multicentre study performed in The Netherlands in which 168 patients, resistant to clomiphene citrate, were randomized to either LOD ($n = 83$) or ovulation induction with recombinant FSH (rFSH, $n = 65$)

Table 18.4 Indications for laparoscopic ovarian diathermy (LOD)

Anovulatory polycystic ovary syndrome
Clomiphene citrate resistance
Persistent hypersecretion of luteinizing hormone
Repeated over-response to clomiphene citrate or gonadotrophins
Patients who find it difficult to travel for regular scans
No value for therapy of long-term effects of polycystic ovary syndrome, e.g. hirsutism, obesity

Table 18.5 Strategy for ovulation induction in anovulatory polycystic ovary syndrome

Slim patient	Overweight patient (body mass index >30 kg/m ²)
1. Clomiphene citrate therapy	1. Lifestyle changes
2. LOD if luteinizing hormone elevated	2. Clomiphene citrate therapy
3. Gonadotrophin therapy or LOD if clomiphene citrate resistant	3. Gonadotrophin therapy or LOD if clomiphene citrate resistant
4. IVF if no pregnancy after nine to 12 ovulations	4. IVF if no pregnancy after nine to 12 ovulations

IVF, in-vitro fertilization; LOD, laparoscopic ovarian diathermy.

(Bayram et al 2004). The initial cumulative pregnancy rate after 6 months was 34% in the LOD arm vs 67% in the rFSH arm. Those who did not ovulate in response to LOD were first given clomiphene citrate and then rFSH, so by 12 months, the cumulative pregnancy rate was similar in each group at 67%. Thus, those treated with LOD took longer to conceive, and 54% required additional medical ovulation induction therapy.

Laparoscopic ovarian diathermy is associated with a low risk of multiple pregnancy and so does not need the same intensity of monitoring as the use of drugs to stimulate ovulation. Indications for LOD are listed in Table 18.4. A strategy for ovulation induction for women with PCOS is outlined in Table 18.5.

Conclusions

PCOS is one of the most common endocrine disorders. It may present, at one end of the spectrum, with the single finding of polycystic ovarian morphology as detected by pelvic ultrasound. At the other end of the spectrum, symp-

toms such as obesity, hyperandrogenism, menstrual cycle disturbance and infertility may occur either singly or in combination. Women with PCOS are characterized by the presence of insulin resistance, central obesity and dyslipidaemia, which appears to place them at higher risk of developing diabetes as well as cardiovascular disease. There are a number of environmental factors that may influence the expression of PCOS, in particular a tendency to insulin-resistant states induced by overeating and underexercising. A plausible hypothesis for the survival of PCOS in the population is that of the 'thrifty phenotype/genotype', whereby in times of famine, individuals who have a tendency to obesity preserve the population by maintaining fertility, while those of normal body weight fall below the threshold body weight for fertility. This may explain the greater prevalence of PCOS among South Asians in the UK, where there is relatively greater nutrition and thus the right environment to express PCOS. In addition, the 'thrifty phenotype' hypothesis suggests that in-utero insulin resistance results as an adaptation to impaired nutrition, and this persists through to adult life and is amplified by overnutrition (obesity).

PCOS is probably the same the world over, although without an agreed definition, one cannot say for sure that this is the case. There may be factors that affect expression and presentation, whether because of racial differences in the colour and distribution of hair (e.g. Japanese vs Mediterranean women) or variations in hormone production and receptor activity. Fundamentally, the underlying condition is likely to be the same. Management should be directed towards an individual's needs (whether cosmetic, reproductive or metabolic), and attention should be given to potential long-term sequelae.

Women with PCOS are characterized by the presence of insulin resistance, central obesity and dyslipidaemia, which appears to place them at higher risk of developing diabetes as well as cardiovascular disease. The retrospective long-term follow-up studies have confirmed the higher incidence of diabetes, although they have not shown a higher risk of mortality from IHD. Cross-sectional studies have demonstrated a significant association between PCOS and IHD. Prospective longitudinal studies confirming this risk are still awaited. There does seem to be sufficient biochemical evidence regarding the potential for long-term risks of cardiovascular disease and diabetes, which need to be addressed when counselling women with PCOS. Encouraging weight loss remains the most effective first-line therapeutic intervention in these women, albeit hard to achieve. Further longitudinal studies need to be performed to investigate the natural history of PCOS and its sequelae for the health of women.

KEY POINTS

1. PCOS is the most common endocrine disorder in women (approximate prevalence 20–25%).
2. PCOS is a heterogeneous condition. Diagnosis is made by finding two out of the following three criteria: (i) menstrual cycle disturbance, (ii) clinical or biochemical hyperandrogenism, and (iii) ultrasound detection of polycystic ovaries.
3. Management is symptom orientated.
4. If obese, weight loss improves symptoms and endocrinology and should be encouraged. A glucose tolerance test should be performed for women with a BMI of more than 30 kg/m².
5. Menstrual cycle control is achieved by cyclical oral contraceptives or progestogens.

6. Ovulation induction may be difficult and may require progression through various treatments, which should be monitored carefully to prevent multiple pregnancy.
7. Ovulation induction may be achieved with clomiphene citrate, gonadotrophin therapy or laparoscopic ovarian diathermy.
8. Hyperandrogenism is usually managed with an oral contraceptive containing ethinylestradiol in combination with either cyproterone acetate or drospirenone. Alternatives include spironolactone, flutamide and finasteride, all of which have potential adverse effects.
9. Insulin-sensitizing agents (e.g. metformin) are not indicated in first-line management, and should usually only be prescribed if there is impaired glucose tolerance or frank diabetes.

Introduction

At fertilization, two gametes fuse to generate an embryo which subsequently initiates an elaborate developmental programme whilst negotiating its way to the uterine cavity, the site of implantation. Recent years have seen great strides in our understanding of the molecular minutiae underpinning these events. These advances have furthered insight into human reproductive failure, guided the refinement of treatment designed to alleviate subfertility, and contributed to the evolution of avant-garde scientific developments, most notably stem cell technology.

This chapter provides an overview of fertilization, preimplantation embryonic development and implantation, and their collaboration in reproduction. The chapter will begin by outlining the essential prerequisites for fertilization, and conclude with a bird's eye view of some of the clinical and scientific innovations that have been mined from an improved understanding of these elaborate processes.

Prelude to Fertilization

Sexual dimorphism in gametogenesis

Male gametes (spermatozoa) and female gametes (ova or eggs) possess half the normal chromosome complement. The merging of two gametes at fertilization restores the complete chromosome set in the embryo.

Spermatogenesis and oogenesis produce male and female gametes, respectively, and are characterized by a unique nuclear division, known as 'meiosis', which halves chromosome numbers. Notably however, the tempo of gametogenesis differs markedly between males and females. Spermatogenesis progresses uninterruptedly over approximately 60–70 days, whereas oogenesis often spans decades

and is a discontinuous process punctuated by two arrest stages (Homer 2007).

With the exception of the relatively small amount of DNA associated with mitochondria which is exclusively oocyte-derived, spermatozoa and eggs have comparable stakes in the embryo's genetic blueprint. In stark contrast, male and female gametes make very different cytoplasmic contributions (Figure 19.1). Virtually all of the embryo's biosynthetic raw materials and organelles are derived from the egg, with the centriole being the only male cytoplasmic contribution. The fate of an embryo is therefore critically dependent upon stores built up in the oocyte during an extended growth phase lasting 2–3 months, resulting in a 100-fold increase in oocyte volume (Telfer and McLaughlin 2007). Consequently, any compromise to egg quality, such as is seen with advancing female age, has devastating consequences for embryonic and reproductive potential (Homer 2007). Accordingly, older women experience lower in-vitro fertilization (IVF) success rates, along with increased risks for miscarriage and chromosomally abnormal offspring.

In stark contrast to oogenesis which has embryonic sustenance as an over-riding concern, spermatogenesis aims to produce a lightweight and motile gamete capable of penetrating the oocyte. Spermatogenesis fulfils this objective by incorporating a remodelling phase known as 'spermiogenesis', the most remarkable cellular metamorphosis in the human body. Spermiogenesis strips the spermatid of almost all of its cytoplasm, makes the nucleus highly compact by integrating unique DNA-binding proteins called 'protamines' (Sassone-Corsi 2002), and fashions a propulsive tail with an adjacent fuel source in the mitochondria-laden mid-piece (Figures 19.2 and 19.3). A specialized lysosomal-like secretory granule known as the acrosome is also forged, forming a cap-like structure over the nuclear surface (Figures 19.2 and 19.3). The acrosome contains enzymes essential for

Figure 19.1 Colour-enhanced scanning electron micrograph of human sperm attempting to fertilize an egg. Note the marked difference in size between the spermatozoa and the egg. *Reproduced with permission from the Wellcome Trust.*

digesting a path through the egg's outer covering known as the 'zona pellucida'.

Maturation and capacitation

On release into the seminiferous tubule lumen, spermatozoa are immotile and lack fertilizing capacity, only acquiring these facets after maturation and capacitation.

Maturation occurs in the epididymis endowing spermatozoa with the potential for movement and fertilization. The molecular basis for maturation remains unresolved, but is known to depend upon androgens and exposure to the dynamic microenvironment created by the secretory and absorptive functions of the epididymal epithelium (Nixon et al 2007).

Capacitation enables spermatozoa to recognize their full fertilization potential and occurs within the female genital tract. It is characterized by cyclic adenosine monophosphate (cAMP)-dependent tyrosine phosphorylation of intracellular proteins, most of which are components of the sperm exocytotic and motility machinery (Nixon et al 2007). The capacitated spermatozoon is now distinguished by hyper-activated motility and a change in surface membrane properties, rendering it sensitive to signals encountered in the immediate vicinity of the ovulated egg.

Transport of gametes in the female genital tract

At coitus, sperm are deposited in the upper vagina and on the external cervical surface. In spite of coagulum formation, more than 99% of sperm are lost by leakage from the vagina, with only a small minority gaining access to the relative haven of the cervical crypts. From there, only about one in every million spermatozoa will successfully navigate the 16–20-cm journey to the tubal ampulla, propelled by innate motility and aided by currents created by tubal ciliary activity.

At the time of ovulation, the egg and its tunic of cumulus cells are directed by tubal fimbria and cilia into the tubal

ostium and then towards the tubal ampulla (Figure 19.4). The cumulus–egg complex attracts sperm by releasing chemoattractants that stimulate sperm odorant receptors, thereby inducing cAMP-mediated sperm chemotaxis.

Fertilization

Fertilization commences with spermatozoal penetration of the oocyte's outer coverings, and concludes with syngamy,

the amalgamation of male and female paternal genomes on the first mitotic spindle, altogether lasting approximately 18–21 h.

Cumulus penetration

The first obstacle encountered by any would-be suitor of the ovulated egg is a covering of cumulus cells embedded in an extracellular matrix comprised primarily of the glycosaminoglycan, hyaluronan (Figure 19.5A). Spermatozoa digest a path through the extracellular matrix via hyperactivated motility and a glycoposphatidyl inositol (GPI)-anchored surface hyaluronidase termed 'PH-20' (Primakoff and Myles 2002). Notably, eggs influence sperm penetration, albeit indirectly, by secreting factors such as growth differentiation factor-9 and bone morphogenic protein-15 which regulate cumulus integrity (Swain and Pool 2008).

Sperm–zona interaction

After cumulus penetration, sperm must engage and penetrate the zona pellucida (Figure 19.5B and C). The zona is secreted by the growing oocyte and, in humans, comprises four glycoproteins: ZP1, ZP2, ZP3 and ZP4 (Wassarman 2008). ZP3 in concert with O-linked oligosaccharides functions as the primary sperm receptor that preferentially binds the plasma membrane overlying the intact acrosome. ZP2 is postulated to serve as a secondary receptor that attaches to the inner acrosomal membrane of acrosome-reacted sperm. The zona is also important for mediating species specificity in gamete interaction, and for preventing polyspermy following the cortical reaction (discussed later).

The complementary spermatozoal ligand for ZP3 defies unequivocal identification at present. It appears that the coordinated action of several proteins such as GalTI-1

Figure 19.6 Acrosome reaction.

(β -1,4-galactosyltransferase) and SED1 that are recruited and constrained by lipid rafts on the sperm surface may mediate docking of sperm on to the zona (Nixon et al 2007).

Binding of sperm ligands with ZP3 induces a rise in intracellular calcium, triggering multiple sites of fusion between the sperm membrane and the outer acrosomal membrane (Figure 19.6). This culminates in exocytosis of sperm acrosome contents, the acrosome reaction (Figures 19.5B and 19.6). The proteases and glycosidases thus released, in concert with hyperactivated motility, enable sperm to digest a path through the zona (Figure 19.5B).

Sperm–egg binding and fusion

Having penetrated the zona, spermatozoa enter the perivitelline space between the egg membrane (oolemma) and the zona (Figure 19.5B). Here, further receptor–ligand interactions enable binding of equatorial sperm membrane and oolemma, followed by insertion of the sperm membrane into the opposing oocyte bilayer at fusion (Figure 19.5C).

Initial interest in interplay between oolemmal integrins (e.g. $\alpha 6 \beta 1$) and sperm disintegrins (e.g. fertilin and cyrillin) as mediators of binding–fusion have dissipated due to lack of corroborative evidence from integrin/disintegrin knockout mouse models. Instead, focus is currently on alternative candidates such as sperm lysozyme-like protein and Izumo on sperm, and GPI-anchored proteins and the CD9 tetraspanin on eggs (Kaji et al 2000, Nixon et al 2007).

Egg activation

Sperm–egg fusion induces calcium oscillations in the egg emanating from the point of sperm entry. These calcium transients result from inositol triphosphate production brought about by a soluble sperm-specific factor known as ‘phospholipase-C ζ ’ (Swann et al 2006). Calcium signals

induce the two principal events associated with egg activation: breaking the second meiotic arrest and the cortical reaction.

At the time of fusion, the egg is arrested in meiosis II. This state of suspended animation is dependent upon maturation-promoting factor that is itself sustained by an ooplasmic activity known as ‘cytostatic factor’ (Tunquist and Maller 2003). The recent characterization of two proteins, early mitotic inhibitor 2 and the calcineurin phosphatase, has elucidated the link between calcium and meiosis II resumption. Following fusion, the ensuing calcium surge induces calcium/calmodulin-dependent-kinase-II-dependent early mitotic inhibitor 2 destruction and transient calcineurin activation, together resulting in cytostatic factor and maturation-promoting factor inactivation and relief from meiosis II arrest (Mochida and Hunt 2007, Wu and Kornbluth 2008).

In response to rising intracellular calcium levels in the egg, specialized organelles known as ‘cortical granules’ migrate towards and fuse with the oolemma, thereby releasing their enzyme contents into the perivitelline space. This so-called cortical reaction serves to impose a block to polyspermy by a number of mechanisms. These include the cleavage of ZP3 oligosaccharides by β -hexosaminidase B thereby removing receptors for sperm binding, and ZP cross-linking making the zona impenetrable to sperm.

Formation of pronuclei and syngamy

Following fusion, the sperm nucleus enters the ooplasm accompanied by its centriole and flagellum. The male centriole is required for nucleating spindle microtubules and thus for cell division, the female equivalent having been lost during the oocyte’s growth stage. On entering the ooplasm, sperm nuclear membranes dissolve and the highly condensed male chromatin undergoes decondensation as its constituent protamines are reduced by glutathione and ultimately replaced by histones present in the ooplasm.

Pronuclei formation in the resulting zygote involves the reformation of a nuclear envelope around each of the haploid parental genomes. The pronuclei migrate towards one another and their constituent chromosomes undergo replication in preparation for the first mitotic division of the embryo. Following DNA duplication, pronuclear membranes break down, and the maternal and paternal chromosomes come together for the first time on the first mitotic spindle at syngamy. Immediately thereafter, chromosomes move apart at anaphase, the cleavage furrow forms and the one-cell zygote becomes a two-cell embryo.

Preimplantation

Preimplantation development encompasses the period from fertilization to implantation. Key events occurring during this time include continued cell division, morphological refashioning and genetic reprogramming.

Timelines and key morphologic changes of embryonic development

During early embryonic divisions, increasing cell number is not accompanied by any appreciable increase in embry-

onic size, reflected by the continued presence of the zona (Figure 19.7). Instead, during this time, the cytoplasm inherited from the egg is merely redistributed to the accumulating blastomeres which get progressively smaller, again vividly illustrating the central role played by the egg in embryogenesis.

Around the eight-cell stage (3–4 days post ovulation), the embryo undergoes compaction whereby membrane surfaces between neighbouring embryonic cells (or blastomeres) become indistinct, leading to the formation of a morula by the 16-cell stage. Around this time, the embryo enters the uterine cavity to begin its rapport with the endometrium (Figure 19.7). Shortly thereafter, at the 32–64-cell stage (4–5 days post ovulation), the blastocyst is formed, characterized by the presence of a cavity or blastocoel and the presence of two cell types: an outer trophoctoderm (TE) or trophoblast which is the placental precursor, and an eccentrically placed inner cell mass (ICM) which is the progenitor of the embryo proper (Figure 19.7). As discussed in greater detail later, isolation and culture of cells from the inner cell mass at this stage results in the derivation of an embryonic stem (ES) cell line (see Figure 19.10C).

Oviductal transport and nutritional support

Tubal embryo transport is dependent upon coordinated oviductal smooth muscle activity mediated by the sympathetic nervous system. The emerging picture is that sympathetic tone requires fine-tuning by lipid mediators, known as 'endocannabinoids' (e.g. anandamide), acting via CB1 receptors. Human fallopian tubes were recently shown to express CB1, the levels of which peak during the luteal phase, likely reflecting control by progesterone (Horne et al 2008). The importance of endocannabinoid signalling is underlined by high rates of oviductal embryo retention in

CB1-deficient mice (Wang et al 2004), and lowered tubal CB1 expression in women with ectopic pregnancies (Horne et al 2008).

The embryo's nutritional requirements change during early development. Thus, the early-cleavage-stage embryo is relatively metabolically quiescent and utilizes pyruvate as an energy source, whereas blastocysts demonstrate high metabolic activity and use glucose as their sole energy supply. In response to this, the oviduct is rich in pyruvate and non-essential amino acids, and low in glucose, whereas the uterine cavity is rich in glucose and essential amino acids (Watkins et al 2008).

Genetic aspects: embryonic reprogramming to embryonic genome activation

Underlying the overt structural changes described above are dramatic alterations in the regulation of gene expression. Under the influence of ooplasmic factors, the specialized gene expression programmes of both male and female gametes are largely erased to provide a *tabula rasa* on which to establish a well-orchestrated embryonic gene expression pattern required for preimplantation development (Niemann et al 2008).

This reprogramming is imposed by epigenetic modifications consisting of changes to DNA methylation status and to the histones on which the DNA is wound (Egli et al 2008). By altering the accessibility of DNA to the transcription machinery, epigenetic changes alter gene expression without altering the core genetic code. Epigenetic reprogramming is ultimately responsible for the acquisition of totipotency by early embryonic cells, conferring on them the capacity to form any cell type in the body, including extra-embryonic trophoblast.

Figure 19.7 Timeline of preimplantation embryonic development during transit of the embryo through the fallopian tube and into the uterine cavity. From Wang and Dey; Roadmap to embryo implantation: clues from mouse models; *Nature Reviews Genetics*, 7;185–199,2006.

One group of genes must, however, remain shielded from this global reprogramming effort. These are the imprinted genes for which it is critically important that a parent-of-origin-specific pattern of expression is retained (Swales and Spears 2005). Male and female imprints are laid down during gametogenesis, and must be sequestered away from the reprogramming route if proper embryonic development is to follow.

Until its own genome is fully activated, the early embryo is heavily reliant on maternal transcripts present in the egg for directing new protein synthesis integral to early development. As epigenetic marks are laid down, the embryonic genome becomes progressively activated. Synchronous with this embryonic genome activation (EGA) is the degradation of oocyte-derived transcripts, thereby marking a maternal-to-embryonic baton change in genetic control. The major EGA burst occurs at the four-cell stage in humans and at the two-cell stage in mice. Recent evidence from mice suggests that EGA occurs in three successive and overlapping waves comprising minor and major EGA and mid-preimplantation EGA (Wang and Dey 2006).

Expression of specific genes is required for segregation of the TE and ICM lineages at the morula-to-blastocyst transition. The current consensus is that *Nanog* and *Oct4* are required for ICM specification and for suppressing the formation of extraembryonic lineages. On the other hand, *Cdx2* is required for TE specification by ensuring the repression of *Oct4* and *Nanog* in the TE (Wang and Dey 2006).

Implantation

Having entered the uterine cavity, the trophoectoderm of the free-living blastocyst engages in foreplay with the endometrial luminal epithelium in the hope of securing a

reliable nutrient supply. Successful implantation is the culmination of a highly intricate molecular dialogue between an implantation-competent blastocyst and a receptive endometrium. The process of implantation is schematically shown in Figure 19.8, but involves a series of complex biological interactions between the embryo and endometrium to be successful.

Morphologic changes and the window of implantation

Implantation requires the simultaneous presence of an activated embryo and a receptive endometrium. The endometrium is only receptive during a restricted timeframe referred to as the 'implantation window'; prior to this window, the endometrium is prereceptive, whilst afterwards it is refractory and hostile to blastocyst survival. In humans, the receptive phase occurs approximately 5–9 days following ovulation, corresponding to days 20–24 of an idealized 28-day cycle (Diedrich et al 2007).

The principal regulators of uterine receptivity are oestrogen and progesterone acting via nuclear oestrogen receptors ($ER\alpha$ and $ER\beta$) and progesterone receptors ($PR\alpha$ and $PR\beta$). Endometrial expression of the homeobox gene, *HOXA-10*, rises dramatically at implantation and conveys progesterone responsiveness within the uterine stroma (Achache and Revel 2006). Oestrogen induces epithelial and stromal proliferation as well as PR expression. Progesterone, on the other hand, promotes stromal transformation or decidualization, glandular secretion and vascular remodelling. Bleb-like protrusions called 'pinopods' that extend beyond the epithelial microvilli tips are also under the influence of progesterone. Pinopods are preferential sites of embryo–endometrial interactions (see Figure 19.9C) and may serve

Figure 19.8 Stages of implantation.

Figure 19.9 Schematic model of the roles of L-selectin and trophinin in human implantation. (A) The blastocyst expresses L-selectin and is proposed to 'roll' along the glycocalyx-covered endometrial surface epithelium. MUC1 in the glycocalyx prevents embryonic adhesion except in areas expressing L-selectin ligand. (B) Human chorionic gonadotrophin (hCG) secreted by the blastocyst induces localized expression of trophinin by the endometrial epithelium. (C) Trophinin is concentrated on pinopods which project above the glycocalyx layer. In order to facilitate adhesion, the glycocalyx adjacent to the embryo is attenuated, allowing for direct trophinin–trophinin interaction between pinopods and the trophoblast.

as morphological markers of uterine receptivity (Achache and Revel 2006).

The process of implantation is classified into three stages that form a continuum: apposition, adhesion and penetration. Thinning of the epithelial glycocalyx layer, retraction of long apical microvilli, and proteolytic digestion of the zona pellucida enable endometrial and trophoblastic microvilli to interdigitate. Shortly after attachment, the underlying stroma exhibits increased vascular permeability and oedema, alterations in intercellular matrix, sprouting of new capillaries and altered stromal cell morphology, collectively referred to as the 'primary decidualization reaction'. After 2–3 days, this reaction is more pervasive, giving rise to the secondary decidua as preparation of the major endometrial component of the placenta gets underway.

Within a few hours of attachment, penetration follows as trophoblastic processes erode the basal lamina. Implantation is described as interstitial in humans by virtue of the fact that the embryo invades the stroma deeply enough for the luminal epithelium to be reconstituted over it (Figure 19.8). Some trophoblastic cells fuse, forming the syncytiotrophoblast, whilst others retain their cellularity and serve

as a trophoblastic reservoir known as the 'cytotrophoblast' (Figure 19.8). Maternal blood vessels are eroded so that the syncytiotrophoblast is bathed in maternal blood. These initial steps form the basis for the establishment of the elaborate placental circulation, the details of which can be found in textbooks devoted to obstetrics.

Molecular cross-talk during implantation

Next, this chapter will describe some of implantation's bewildering molecular entourage. A recurring theme is that of reciprocal interactions between receptor–ligand pairs on the embryo and endometrium reminiscent of sperm–egg interplay during fertilization. Furthermore, it has become evident that the embryo is not merely a passive spectator, but actively directs many aspects of the implantation process.

Adhesion molecules and mucins

Members of the cell adhesion molecule (CAM) family, such as selectins, integrins and cadherins, positively regulate embryo–endometrial interaction (Achache and Revel 2006,

Guzeloglu-Kayisli et al 2007). Embryonic L-selectin interacts with luminal epithelial oligosaccharides (e.g. MECA-79), constituting an initial step in the attachment process (Genbacev et al 2003) (Figure 19.9A). The trophoectoderm expresses another adhesion molecule termed 'trophinin', which is also expressed on endometrial pinopods under the influence of human chorionic gonadotrophin (hCG) secreted by the blastocyst (Fukuda and Sugihara 2008) (Figure 19.9B and C). The ensuing trophinin–trophinin interaction is proposed to be a more potent bond than that mediated by L-selectin (Fukuda and Sugihara 2008) (Figure 19.9C). Although the L-selectin/trophinin system is crucial for human implantation, it appears to be dispensable in mice.

Attachment is further facilitated by integrins such as trophoblastic $\alpha 1 \beta 1$ and endometrial $\alpha V \beta 3$ which bind to ligands such as osteopontin and oncofetal fibronectin on the luminal epithelium and trophoblast, respectively (Achache and Revel 2006). During the proliferative phase, high oestrogen levels acting via $ER\alpha$ inhibit $\alpha V \beta 3$ expression, whilst secretory-phase progesterone has the opposite effect possibly via increased epidermal growth factor (EGF) in combination with downregulation of $ER\alpha$ levels. Interestingly, the embryo may upregulate $\beta 3$ integrins via its interleukin-1 (IL-1) system, thereby actively participating in establishing endometrial receptivity. Calcium-regulated expression of E-cadherin mediated by progesterone and endometrial calcitonin is also thought to contribute to implantation.

In contrast to CAMs, glycoproteins known as 'mucins' (e.g. MUC1) extend beyond the glycocalyx and sterically inhibit adhesion (Achache and Revel 2006) (see Figure 19.9). Although data are contradictory, it is felt that under the influence of progesterone, MUC1 levels are locally reduced on pinopods, thereby unmasking CAMs to facilitate embryo–endometrial interaction. Local downregulation of MUC1 at the implantation site, possibly via blastocyst tumour necrosis factor- α -mediated increases in sheddase enzymes, lends further support for an active embryonic input.

Cytokines and growth factors

Leukaemia inhibitory factor (LIF) is a member of the cytokine family whose endometrial expression peaks during the mid- to late-secretory phase. Implantation fails in mutant mice lacking LIF (Stewart et al 1992), and patients suffering from infertility and recurrent implantation failure display suboptimal endometrial LIF expression (Hambartsumian 1998), underscoring a pivotal role for LIF in implantation. Embryonic signals such as hCG and insulin-like growth factor (IGF) may regulate LIF expression. Conversely, LIF may interact with embryonic LIF receptors to mediate trophoblast growth and differentiation.

Three other cytokines, IL-1 (mentioned above), IL-6 and IL-11, peak in the endometrium during the luteal phase, and are also implicated in implantation.

Growth factors constitute another class of proimplantation mediators and include IGF, transforming growth factor- β and the EGF family, the latter embracing EGF itself, heparin-binding EGF-like growth factor (HB-EGF) and amphiregulin, amongst others (Achache and Revel 2006, Guzeloglu-Kayisli et al 2007). In mice, HB-EGF is the earliest molecular marker of implantation, found exclusively at the sites of active blastocysts (Wang and Dey 2006). HB-EGF

derived from blastocysts induces endometrial HB-EGF expression in a paracrine manner, which in turn interacts with blastocyst receptors (ErbB1 and ErbB4). This HB-EGF autoinduction loop induces blastocyst activation, shedding of the zona pellucida and initiation of attachment. HB-EGF function is conserved as its expression in humans is maximal in the late secretory phase, and HB-EGF-expressing cells adhere to blastocyst ErbB4 (Chobotova et al 2002).

Matrix metalloproteinases and prostaglandins

Implantation is characterized by extensive tissue remodeling and vascular changes. Matrix metalloproteinases (e.g. MMP-9), in concert with tissue inhibitors of matrix metalloproteinases (e.g. TIMP-1), mediate controlled matrix degradation during invasion (Guzeloglu-Kayisli et al 2007).

Prostaglandins are members of the eicosanoid family that direct vascular events required for fully executing the implantation process (Achache and Revel 2006, Wang and Dey 2006). Prostaglandins are produced from membrane phospholipids under the consecutive action of phospholipase A_2 (PLA $_2$), cyclo-oxygenase (COX) and prostaglandin synthase enzymes. COX2-derived prostacyclin (PGI $_2$) is the primary prostaglandin produced at the implantation site, where it acts via the peroxisome-proliferator-activated receptor- δ receptor. Prostaglandin-deficient mice, due to lack of either PLA $_2$ or COX2, suffer higher rates of pregnancy failure resulting from delayed implantation. Furthermore, COX2-derived prostaglandins are also implicated in angiogenesis by differentially regulating vascular endothelial growth factor and angiopoietin signalling cascades. Evidence from mice intimates that prostaglandins are a focal downstream signalling target as LIF induces HB-EGF, which is in turn required for COX2 expression. In humans, COX expression is maximal during the menstrual and proliferative phases, and may be important for fine-tuning uterine receptivity during the window of implantation.

Immune Factors in Implantation

Immune tolerance

Although half of its genes are paternally derived, the implanting embryo is able to evade the maternal immune system during normal pregnancy (Trowsdale and Betz 2006). One aspect of immune tolerance is related to the unique expression of human leukocyte antigen (HLA) antigens on extravillous trophoblast cells which display HLA-C, HLA-E and HLA-G molecules, but not HLA-A or HLA-B which mediate allograft rejection. Other likely factors include trophoblastic expression of Fas ligand (CD95L) that promotes apoptosis of activated lymphocytes expressing Fas (CD95), as well as suppression of T-cell proliferation secondary to reduced levels of uterine tryptophan, and the systemic and decidual expansion of regulatory T-cells (CD4 $^+$ CD25 $^+$ Foxp3 $^+$ T-cells).

Uterine natural killer cells

A hallmark of decidualization is the presence of uterine natural killer cells (uNK cells; CD56 bright /CD16 $^+$) which represent 70% of the uterine lymphocyte population at the implantation site (Moffett-King 2002). The term 'killer' is

misleading as there is no compelling evidence that uNK cells kill trophoblast cells; unlike their highly cytotoxic blood counterparts (CD56^{dim}/CD16⁺), uNK cells are of low cytotoxicity. On the contrary, it is currently felt that uNK cells may exert a beneficial effect in controlling trophoblast invasion, possibly mediated via interaction between uNK cell killer immunoglobulin receptor and trophoblastic HLA-C (Moffett and Loke 2006). Given the uncertain role of the uNK cell in human pregnancy and the equally uncertain relationship between blood and uNK cells, tenuous links between blood NK cell levels and risk of pregnancy failure remain of uncertain significance (Moffett et al 2004).

Clinical and Scientific Correlates

Assisted reproductive technology

The world recently celebrated the 30th birthday of Louise Brown, the first IVF baby. Since her birth on 25 July 1978, more than 4 million children have been born worldwide using this technology. As with natural pregnancy, the cornerstones for IVF success centre on good-quality embryos, a receptive endometrium and a productive embryo–endometrial rapport. Some of the advances, controversy and concerns surrounding this powerful technology are described below.

Embryo–endometrial synchronization

A greater appreciation of embryo development has translated into improved IVF success rates by altering parameters to mimic the in-vivo situation more closely. During natural conception, the cleavage-stage embryo (2–3 days post fertilization) is first geared towards interacting with the oviductal milieu, whilst the blastocyst-stage embryo (5–6 days post fertilization) is more temporally synchronized with the endometrium. In keeping with this, significantly better IVF implantation rates accrue after transferring blastocyst-stage embryos into the uterine cavity compared with transferring cleavage-stage embryos (Papanikolaou et al 2008). Culture of embryos to the blastocyst stage in the laboratory setting has become increasingly more achievable with the development of improved sequential embryo culture media. These media formulations have, in turn, arisen from a greater understanding of the evolving needs of the preimplantation embryo during its journey from the oviduct to the uterine cavity.

Embryonic aneuploidy and preimplantation genetic screening

One of the over-arching determinants of embryo quality is chromosome constitution. The presence of too few or too many chromosomes (aneuploidy) is a major contributor to IVF failure and miscarriage.

On this basis, preimplantation genetic screening (PGS) has been pursued to enable the selection of embryos having normal chromosome numbers (euploid). PGS differs from preimplantation genetic diagnosis, which is applied to patients at high risk of transferring a defined genetic disorder. PGS most commonly involves the removal of one

or two cells from the embryo and their subsequent analysis using fluorescence in-situ hybridization to probe for a panel of chromosomes (usually 13, 14, 15, 16, 18, 21, 22, X and Y).

Studies involving PGS have produced conflicting results. The only two completed randomized controlled trials to date did not provide any compelling evidence that PGS improves pregnancy outcomes (Anderson and Pickering 2008). The results of these studies present something of an enigma in so far as there is no *a priori* reason why a euploid embryo should not result in a better outcome than one that is aneuploid. It is only when better diagnostic techniques emerge that are less detrimental to the embryo and which give a more comprehensive readout of the embryo's entire chromosomal constitution (not just a nine-chromosome sample) that the role of PGS in assisted reproductive technology (ART) will be better informed.

IVF/ICSI: proceed with caution

Notwithstanding advances that more closely replicate 'physiological' conditions, there remain aspects of ART that are not normally encountered in spontaneous conception and which justifiably fuel considerable trepidation regarding their potential impact on resulting offspring.

Since its introduction over a decade and a half ago, intracytoplasmic sperm injection (ICSI) has become an established tool for overcoming male factor subfertility (Varghese et al 2007). However, ICSI bypasses many of the stringent natural selection mechanisms detailed previously that would normally preclude successful fertilization by defective spermatozoa. Thus, ICSI will ensure that infertility-related genetic traits such as Y-chromosome microdeletions in the azoospermia factor region are handed down to male offspring. Apart from propagating male infertility traits, it is unknown at present whether such genetic defects harbour any additional, more sinister, consequences. It is notable in this respect that there have been reports of increased rates (albeit small) of congenital abnormalities, especially of the genitourinary system, amongst ICSI-derived offspring. However, because the oldest child conceived through ICSI is still only a teenager, long-term studies are lacking and clarification on any such links, if indeed they do exist, remain outstanding.

Another area of concern is the potential effect of the artificial embryonic environment during IVF on the epigenome, in particular on imprinted genes (Watkins et al 2008).

Stem Cell Technology

The remarkable capacity of the oocyte to reprogramme gametic nuclei following fertilization has contributed to the birth of, arguably, the most exciting and promising scientific endeavour of our generation: somatic-cell nuclear transfer (SCNT) and the generation of embryonic stem cells (ES cells) (Hochedlinger and Jaenisch 2003).

Somatic-cell nuclear transfer

SCNT denotes the introduction of a donor somatic cell nucleus into an enucleated egg (Hochedlinger and Jaenisch

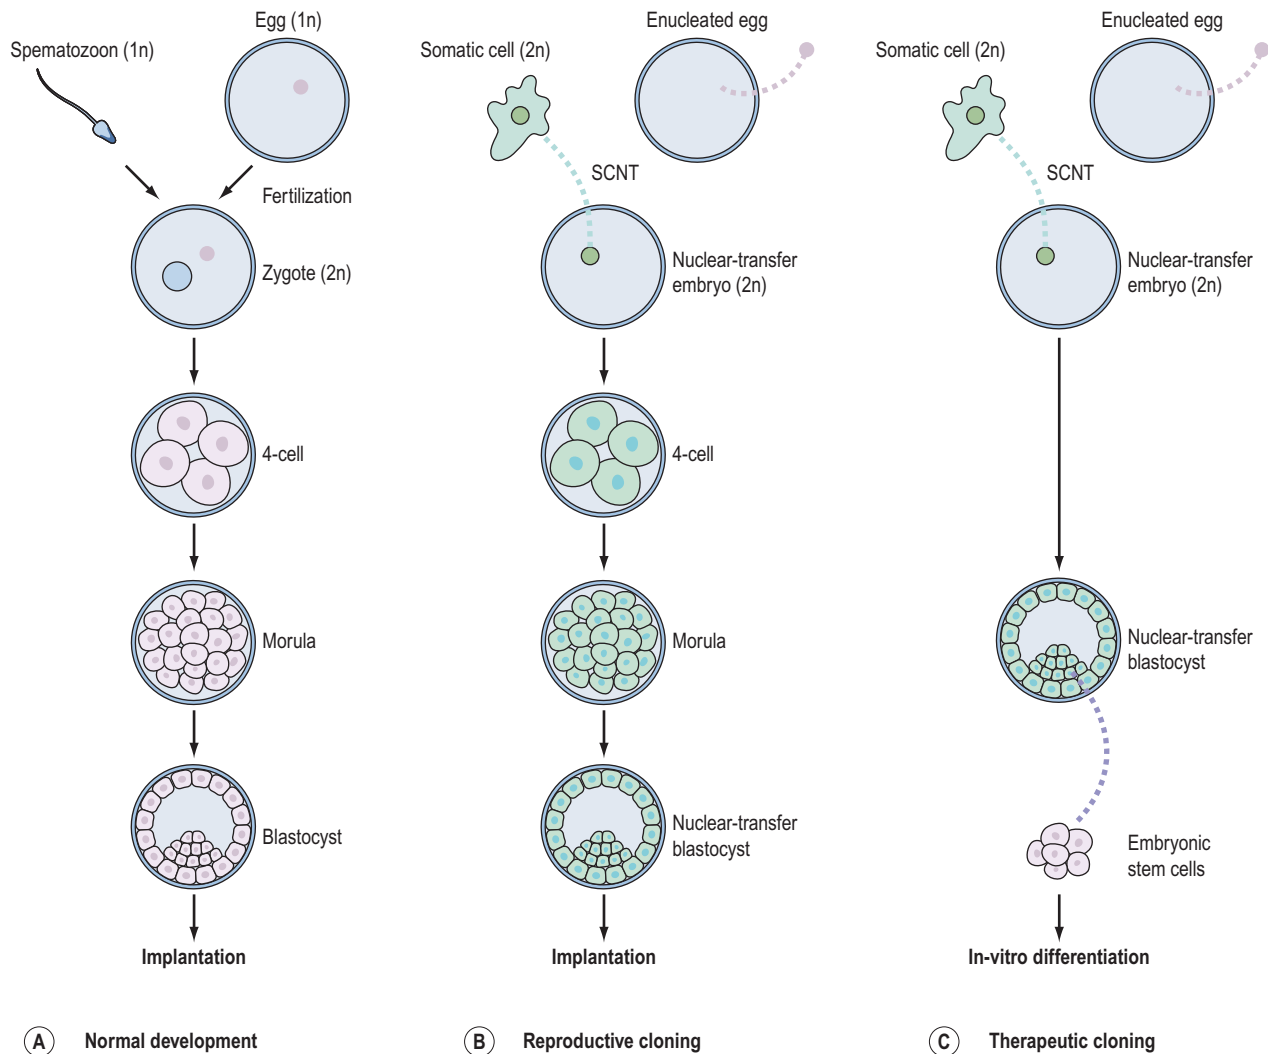

Figure 19.10 Schematic comparison of natural fertilization and embryonic development with reproductive and therapeutic cloning. (A) During normal fertilization and in-vitro fertilization, spermatozoa and eggs containing half the chromosome complement ($1n$) fuse to reconstitute the complete diploid chromosome set ($2n$) in the zygote. Subsequent embryonic development produces a morula followed by a blastocyst, at which stage implantation occurs. (B) During reproductive cloning, the diploid nucleus of an adult donor cell is introduced into an enucleated oocyte which can be activated to commence embryonic development to the blastocyst stage. Following transfer of such cloned blastocysts into surrogate mothers, a small proportion will implant and develop into an animal that is the clone of the animal from which the adult donor cell was derived. (C) The initial steps of therapeutic cloning are similar to reproductive cloning up until blastocyst development. At this stage, instead of transferring the blastocyst into a surrogate mother, cells from the inner cell mass are explanted in culture to yield a line of embryonic stem cells that can potentially differentiate in vitro into any type of cell for therapeutic purposes. SCNT, somatic-cell nuclear transfer.

2003) (Figure 19.10B). The transcriptional programme of the donor nucleus is erased by ooplasmic factors and reprogrammed towards an embryonic schedule of development. Once activated using an artificial stimulus, the egg containing the donor nucleus can then be coaxed into developing into a so-called 'cloned' blastocyst in the same way that an egg fertilized by a spermatozoon can develop into a blastocyst during IVF. Notably, unlike the IVF embryo which is a genetic composite of two gametic genomes, the SCNT embryo is genetically identical to that of (or a clone of) the donor somatic cell (Figure 19.10, compare A and B). The first cloned human blastocysts derived after SCNT with human ES cells (Stojkovic et al 2005) and adult fibroblasts (French et al 2008) have been reported recently.

'Reproductive cloning' and 'therapeutic cloning'

The blastocyst resulting from SCNT could be transferred into a recipient uterus with the aim of producing cloned offspring with the identical genetic composition of the donor nucleus (Figure 19.10B). Although highly inefficient, such 'reproductive cloning' has resulted in the birth of animals from 12 species, the first mammalian clone being 'Dolly the sheep' (Wilmut et al 1997). Importantly, however, human reproductive cloning is unanimously considered morally and ethically repugnant, and is legally prohibited in the UK by the Human Reproductive Cloning Act (2001) (Lovell-Badge 2008).

The overwhelming interest in this field does not surround 'reproductive cloning' but instead centres largely on 'therapeutic cloning'. For therapeutic cloning, cells from the inner cell mass of an SCNT blastocyst are explanted in culture to yield a line of pluripotent ES cells potentially capable of differentiating into any adult cell type (Hochedlinger and Jaenisch 2003) (Figure 19.10C). ES cell lines have recently been derived from primates following SCNT (Byrne et al 2007).

Regenerative medicine: the potential benefit of nuclear reprogramming

One of the ultimate goals of this technology is the laboratory generation of 'customized' patient-specific cells of any tissue type for use in regenerative therapies. For example, neurones engineered in a culture dish from ES cells might be made available for treating neurodegenerative diseases. Importantly, being autologous, such patient-specific cells circumvent immunocompatibility issues that severely limit the utility of more conventional tissue transplantation approaches.

Nuclear reprogramming technology also provides avenues for cell-based drug discovery and for more fundamental research into understanding embryonic development, the genetic basis for disease and the molecular circuitry underpinning cellular differentiation.

Alternative methods of nuclear reprogramming

One of the major obstacles to stem cell research is the dearth of human oocytes available for SCNT (Hall and Stojkovic 2006). One means for sidestepping this problem is the star-

ling revelation that nuclear reprogramming could be effected by a cocktail of just four transcription factors (OCT4, SOX2, KLF4 and MYC) to produce so-called 'induced pluripotent stem' (iPS) cells (Okita et al 2007). This is a field that is progressing with unprecedented rapidity, driven by the goal of regenerative medicine. There are clear links between the nuclear reprogramming events that underpin the earliest events of embryo development and the molecular processes that are needed to reprogramme an adult nucleus. It is anticipated that our understanding of the latter may lead to explanations for many of the problems that occur during human fertilization and preimplantation development.

Concluding Remarks

Relentless scientific toil, largely undertaken in animal models like the mouse, has made us privy to many of the molecular forces driving critical stages in mammalian reproduction. However, it is becoming increasingly evident that humans exhibit unique signalling details that are not replicated in animal models (Diedrich et al 2007, Childs et al 2008, Fukuda and Sugihara 2008). It will therefore be important that greater inroads be made into the workings of the human system if clinical practice is to be better served. In the future, techniques such as gene expression profiling will lead to a better appreciation of the molecular signature defining a receptive human endometrium (Diedrich et al 2007). The growing emphasis on single embryo transfer during IVF as a means for reducing unacceptably high multiple pregnancy rates places greater burden on selecting the best quality embryos (Cutting et al 2008). In this regard, the application of metabolomics, proteomics and comparative genomic hybridization to embryo selection holds promise for 'sifting the wheat from the chaff'.

KEY POINTS

1. Gametogenesis produces spermatozoa and eggs via meiosis, which reshuffles genetic material and halves chromosome numbers. Fusion of gametes at fertilization restores the full diploid chromosome complement in the embryo.
2. In order to attain full fertilization potential, spermatozoa undergo maturation in the epididymis followed by capacitation in the female genital tract. The vast majority of the embryo's cytoplasm and its component organelles are derived from the egg, the quality of which is therefore a major determinant of embryo quality and hence reproductive performance.
3. At ovulation, the egg with its outer zona pellucida is surrounded by a covering of follicle-derived cumulus cells embedded in a glycoprotein matrix comprised predominantly of hyaluronan. Fertilization involves spermatozoal penetration of cumulus cells, interaction with and penetration of the zona pellucida, and binding and fusion between the spermatozoal and egg membranes.
4. Spermatozoa penetrate the cumulus cell covering by means of hyperactivated motility and a surface-anchored hyaluronidase. Having penetrated the cumulus covering, interaction of spermatozoal surface ligands with an egg receptor comprising zonal glycoproteins (ZP2 and ZP3) induces the acrosome reaction.
5. The acrosome is a lysosomal-like secretory granule that forms a cap-like structure over the spermatozoal nucleus. The acrosome reaction involves a calcium-mediated release of enzymes which, in concert with hyperactivated motility, enable a spermatozoon to penetrate the zona pellucida and enter the perivitelline space where fusion occurs.
6. At the time of fusion, a soluble sperm factor known as 'phospholipase-C' is introduced into the metaphase-arrested egg, resulting in calcium transients which break the egg's meiotic arrest and induce the cortical reaction so as to prevent polyspermy.
7. Nuclear envelopes assemble around the male and female genomes to form pronuclei in what is now referred to as a 'zygote'. Following DNA replication, pronuclear membranes break down, and male and female chromosomes intermingle for the first time on the first mitotic spindle at syngamy.
8. The embryo increases its cell numbers forming a morula (16 cells) by 3–4 days post ovulation and a blastocyst (32–64 cells) by 4–5 days post ovulation. The blastocyst is characterized by the presence of a fluid-filled cavity or blastocoel along with two cell types: an outer trophoctoderm which is the placental precursor, and the inner cell mass which gives rise to the embryo proper.

9. The ooplasm possesses a unique capacity to reprogramme nuclei into an embryonic pattern of gene expression. Maternal transcripts inherited from the egg direct protein synthesis in the early embryo until embryonic genome activation occurs.
10. Implantation proceeds through three stages (apposition, adhesion and penetration) and requires a receptive endometrium that is present during a limited interval known as the 'implantation window'. The principal mediators of receptivity are oestrogen which promotes epithelial and stromal proliferation, and progesterone which induces decidualization and glandular secretion.
11. A multitude of molecular factors are proposed to mediate implantation including CAMs (e.g. L-selectin and trophinin), cytokines (e.g. LIF), growth factors (e.g. HB-EGF), matrix metalloproteinases and prostaglandins (e.g. prostacyclin).
12. Maternal immune system tolerance to the embryo is mediated by factors such as a unique profile of trophoblastic HLA expression and an increase in decidual regulatory T-cells. The role of uterine and blood NK cells in pregnancy failure remains uncertain.
13. ART success rates have improved through a better appreciation of normal embryogenesis. One example is blastocyst-stage transfer, which has become possible by improvements in in-vitro embryo culture techniques.
14. Although IVF/ICSI has now become commonplace, it is important to remain cognisant of potential adverse effects, and to continue to monitor offspring born following this technology.
15. SCNT capitalizes on the ability of the ooplasm to reprogramme differentiated nuclei, and involves the transfer of an adult cell nucleus into an enucleated egg. Therapeutic cloning refers to the derivation of ES cells from SCNT embryos, and holds promise for generating replacement tissue in regenerative medicine.
16. The shortage of human oocytes remains a major stumbling block to ES cell technology, and has recently led to alternatives such as iPS cells and growing interest in admixed embryos.

Introduction

The intention of this chapter is to provide an overview of a spectrum of disorders of female reproduction, including infertility, which may present to gynaecologists in clinical practice. Observations on epidemiological issues of importance are made, leading to a discussion of the initial assessment of infertile couples in the setting of primary care. A critique of the place of secondary investigations is provided, under the broad headings of disorders of ovulation, tubal factor infertility, endometriosis and uterine factors, and unexplained infertility. Insights into the pathogenesis of infertility brought about by assisted conception techniques are also examined. The need for integration of services in enabling efficient and accurate assessment of the infertile is emphasized throughout.

Epidemiology

Time to conception

A common definition employed in describing infertility is the inability of a couple to conceive following 12–24 months of exposure to pregnancy. The length of exposure time considered is determined by the observation that in the general population, which would include a proportion of couples with infertility, one would expect the chance of conception in any individual cycle to be 20%. Thus, by 1 year of exposure, approximately 85% of couples would have achieved conception, and once 2 years has elapsed, some 92% would have conceived (Evers 2002). Others have evaluated conception rates in truly fertile couples and found that the expectation of pregnancy at 3, 6, 9 and 12 months was 42%, 75%, 88% and 98%, respectively (Gnoth et al 2003). In practical terms, the failure to achieve pregnancy causes enormous

distress to those affected. For people with fertility problems, using a definition of 1 year to describe infertility is usual, and most will have sought medical advice or assistance by that time. Natural fertility rates decline in association with increasing female age, although in an ultimately fertile group of women, it is not certain that their monthly fecundability (percentage chance of conception) is any less than younger cohorts. It may be sensible to consider specialist referral of women over 35 years of age in advance of 1 year, although it is acknowledged that, in many instances, conception will occur naturally in these cases since it can be assumed that a proportion will not be infertile.

Prevalence

Estimates of the prevalence of infertility in the population will be influenced by the duration of infertility used in the definition and the population studied. The setting of prevalence studies, such as primary care (Snick et al 1997) or hospital clinics (Hull et al 1985), will influence the prevalence figures. Community-based data, which would give an accurate reflection of prevalence within the general population, are limited. It is not surprising, therefore, that existing studies suggest a range of lifetime prevalence of infertility extending from 6.6% to 32.6%. One population-based study in the North East of Scotland (Templeton et al 1990), which took account of conceptions resulting in miscarriage and ectopic pregnancy, found a prevalence of 14% using a 2-year definition.

A number of factors have been a matter of concern in recent years with respect to their potential impact on the prevalence of infertility, including the incidence of sexually transmitted infection such as *Chlamydia trachomatis* in the young (Macmillan and Templeton 1999). In addition, there have been suggestions that environmental factors may affect male fertility (Oliva et al 2001), and one should wonder

about the possible effects on female fertility of delayed child-bearing as determined by changes in lifestyle and working patterns. Despite these legitimate concerns, when the population-based study was repeated (Bhattacharya et al 2009), the observed prevalence of infertility had not increased in North East Scotland in the succeeding 20 years.

A lack of observed change in prevalence should not encourage complacency in respect of public health responsibilities. While opportunities to prevent infertility are limited, encouragement to the young to engage in safe sexual practices, limiting exposure to risk of sexually transmitted infection, is clearly important. For teenage girls, rubella immunization programmes should be in place and human papillomavirus vaccination programmes are now being established. Education of the public about the known decline in fertility which occurs with age, particularly in females over 35 years of age, is also important. In addition, the need for folic acid supplementation for women to reduce the risk of neural tube defects should be promoted, as well as the need to make certain lifestyle adjustments on issues such as the potential need to moderate levels of smoking and alcohol consumption, as well as achieving optimal weight. There is convincing evidence that smoking, active or passive, affects reproductive performance in women and men, as well as increasing the risk of small-for-gestational-age infants, stillbirth and infant mortality (National Collaborating Centre for Women's and Children's Health for the National Institute of Clinical Excellence 2004).

The requirement to take account of future reproductive needs in women is essential where abdominal or pelvic surgery is carried out, and careful technique should be employed to minimize the risk of pelvic adhesions. Where uterine instrumentation is considered, particularly in women under 25 years of age, the prevention of *Chlamydia* infection is receiving appropriate attention (Macmillan and Templeton 1999). Screening tests to detect the organism in first-void urine samples or cervical swabs using nucleic acid amplification techniques should be available routinely, and antibiotic treatment should be given for identified cases and potential contacts. Good lines of communication to sexual health and genitourinary medicine services will facilitate swift management.

Diagnostic categories

The management of people with infertility problems is largely dictated by the major diagnostic category in which they fit. Typical figures are shown in Table 20.1.

Diagnostic categories in most studies include male factors, disorders of ovulation, tubal factors, endometriosis and unexplained infertility. The distribution of causes, when analysed, will be affected by whether the female has been pregnant in the past (i.e. secondary infertility). This has an association with an increased risk of tubal factor infertility compared with those couples with primary infertility (i.e. where there has not been a pregnancy in the past) (see Chapter 21, Disorders of male reproduction, for more information). The possibility that male factors may contribute to a couple's infertility should not be ignored, even where the man has fathered a pregnancy in the past. It should be borne in mind that more than one factor may contribute to a couple's infertility, and each may require simultaneous manage-

Table 20.1 Diagnostic categories and distribution of couples with primary and secondary infertility

Diagnostic category	Infertility	
	Primary (%)	Secondary (%)
Male factor	25	20
Disorders of ovulation	20	15
Tubal factor	15	40
Endometriosis	10	5
Unexplained	30	20

ment; for example, ovulation induction for a woman who is not ovulating, in combination with donor insemination. Decisions to initiate active treatment will be influenced by the age of the female, the duration of infertility, and whether or not there has been a pregnancy in the past. Initiating intrusive and potentially harmful treatment should take account of natural expectations of pregnancy. In many instances, expectant management will be appropriate.

Initial Assessment

When to refer

The point at which any couple might seek assistance will be influenced by a number of factors, not least the degree of anxiety which couples feel in confronting seemingly relentless monthly disappointments. It should be borne in mind that libido and, consequently, coital frequency may be influenced by the experience of infertility and thus affect prognosis. While there is some evidence that sperm parameters may be adversely affected by very frequent ejaculation, the evidence suggests that fertility potential is unaffected. Bearing in mind that sperm can be expected to survive for up to 7 days within the female reproductive tract, couples should be advised to have intercourse every 2–3 days to optimize the chance of conception. The use of temperature charts or ovulation [luteinizing hormone (LH)] prediction kits to time intercourse should be discouraged.

It may be apparent to individuals that they may be at risk of a fertility problem, and advice may be sought at an early stage. For example, the male may have had a vasectomy, or undergone testicular surgery in childhood, e.g. orchidopexy; either partner may be a survivor of childhood cancer and have undergone chemotherapy; or the female may be aware of an association of absent or irregular periods with infertility. For some couples, a concern through the high profile which infertility now attracts in the media may have eroded their self-assurance about their fecundity.

In any circumstance, all people seeking advice about fertility should have prompt access to an integrated multidisciplinary service that provides efficient and accurate assessment of their clinical situation. This should lead to individualized care founded on evidence-based principles of management. Care should be reinforced by access to adequate information and appropriate counselling services. At all times, the infertile should be treated with respect and

supported in making informed choices about their clinical management.

Integrated care

Integrated care, by definition, must include the general practitioner (GP), whose role is of fundamental importance (Hamilton 1992). Infertility is a deeply personal problem and many individuals will prefer to discuss intimate matters with someone they know and trust. The counselling support that the GP can provide as preliminary assessment is made and investigations initiated is an excellent foundation for provision of care. Not infrequently, the male and female may be registered with different GPs. This can present difficulties. One should always consider that infertility is a problem affecting both parties, and each may contribute to the pathogenesis. Once referral is made to a specialist clinic, increasing

the demands on couples' time, the intrusive nature of some of the investigations may add to the stress of the situation. Infertility, its investigation and treatment, can threaten domestic stability and it is often the GP, through longstanding knowledge of the couple and their families, who may be in the best position to provide support for those struggling to come to terms with continued disappointment.

All patients should be seen as couples in appropriate surroundings, and the facilities in the surgery should permit examination of both partners. Sufficient time, ideally 30 min, should be made available to permit adequate overall assessment of the problem.

Female assessment: history

Points requiring particular attention in the history and examination of the female are shown in Table 20.2.

Table 20.2 The initial assessment of female infertility: history and examination

Area of investigation	History	Area of investigation	Examination
Infertility	Duration of infertility Length and type of contraceptive use Fertility in previous relationships as well as in present liaison Previous investigation and treatment Subsequent fertility, if known, in any former partners Previous fertility investigations and treatment	General	Height, weight, body mass index Fat and hair distribution (Ferriman Galway score to quantify hirsutism) Note presence or absence of acne and galactorrhoea
Medical	Menstrual history • Menarche • Cyclicity • Pain • Bouts of amenorrhoea • Menorrhagia • Intermenstrual bleeding Number of previous pregnancies including abortions, miscarriages and ectopic pregnancies Any associated sepsis Time to initiate previous pregnancies Past and present drug history, e.g. agents which cause hyperprolactinaemia, past cytotoxic treatment or radiotherapy	Abdominal	Check for abdominal masses or tenderness
Surgical	Previous abdominal or pelvic surgery in particular gynaecological procedures	Pelvis	Assess state of hymen Assess normality of clitoris and labia Assess vagina, looking for problems such as infection, vaginal septa, endometriotic deposits Check for presence of cervical polyps Assess accessibility of the cervix for insemination Record uterine size, position, mobility and tenderness. Perform cervical smear if appropriate
Occupational	Work patterns including separation from partner		
Sexual	Coital frequency and timing, including knowledge of the fertile period Dyspareunia Postcoital bleeding		

Appropriate Initial Investigations

Should couples present to the GP in advance of 1 year of infertility, it may be unnecessary to pursue vigorous investigation unless there is something obvious in either the history or examination. For the GP, it is advisable to ensure that the female is rubella immune and that she is taking folic acid supplementation (0.4 mg/day) to reduce the chance of the fetus developing a neural tube defect. If there is a past history of neural tube defect or the patient is taking antiepileptic medication, a higher dose (5 mg/day) is required.

Merely providing the couple with an outline of their excellent fertility potential over the next year may be all that is required to set their minds at rest. More urgency may be required where the female partner is over 35 years of age.

In the hospital setting, the infertile should have access to advice in a multidisciplinary fertility clinic. It may be helpful for the clinic to employ dedicated liaison staff to assist with the referral process.

The sequence of investigation will be the same regardless of whether the couple are seen for the first time in the GP surgery or the fertility clinic. An explanation of the steps in the process of investigation should be given to the couple at the outset. Three simple questions need to be answered:

- Are sperm available? (i.e. is there evidence of normal spermatogenesis and ejaculatory competence?)
- Are eggs available? (i.e. is the woman ovulating?)
- Can the gametes meet? (i.e. is there a pelvic problem in the female impairing normal gamete/embryo transport and is coital function adequate?)

The principles of investigation of the male will be discussed in detail in Chapter 21. Suffice it to say that semen analysis remains the cornerstone of assessment. In administrative terms, it is helpful if the analysis is done in a dedicated andrology laboratory which serves the fertility clinic, to which onward referral would be made if required.

Disorders of Ovulation

Disturbances in ovulation are the principal factor in approximately 20% of couples presenting to clinics with fertility difficulties. In women who have a regular monthly menstrual cycle (21–42 days), it is most likely that ovulation is occurring normally. The release of the egg from a mature follicle is dependent on the production of a surge of LH by the pituitary gland. This hormonal dynamic initiates the final steps in meiosis, required to allow the oocyte to reach maturity, thus permitting normal fertilization. LH causes the ovarian follicle to rupture and release the egg within; under its influence, the steroid biosynthetic capability of the ovary changes dramatically. Granulosa cells almost exclusively synthesize and release oestradiol in the follicular phase of the cycle, but produce both oestradiol and progesterone during the luteal phase of the cycle. The direct observation of follicular rupture to assess ovulation is not practical in a clinical sense, and thus the release of the oocyte is usually inferred through indirect methods, most often the measurement of progesterone in the putative luteal phase of the cycle.

Presumptive signs of ovulation

Similarly, clinical signs, in addition to regular menstruation, which suggest rather than prove that ovulation is occurring include the presence of Mittelschmerz (mid-cycle abdominal discomfort) or mid-cycle spotting induced through a transient fall in oestradiol coincidental to the LH surge. The production of mid-cycle mucus is oestrogen dependent, and a change in consistency and stretchability (Spinnbarkeit) occurs under the influence of progesterone. This is used in natural family planning techniques as a contraceptive method, but conversely may occasionally have a place in timing intercourse or artificial insemination in promoting fertility. Under the influence of progesterone, basal body temperature (BBT) may rise by 0.5–1.0°C after ovulation. While for some, the finding of such a rise (through serial measurement taken each morning during the periovulatory phase of the cycle) is reassuring, the correlation with serum progesterone levels is poor; couples often find the confusion and uncertainty this brings to be stressful. For this reason, BBT monitoring is not recommended routinely in most clinics.

Measurement of serum progesterone

Serum progesterone levels in excess of 30 nmol/l 7 days after ovulation are usually taken as indicative of satisfactory ovulation, although lower levels are not incompatible with egg release and corpus luteum formation (Hull et al 1982, Wathen et al 1984). This is a retrospective measure of ovulation in so far as the peak level of progesterone is found after egg release. It is important to relate progesterone levels to the timing of subsequent menstruation. Samples will typically be checked on day 21 of a 28-day cycle. Serial checks will be required if the cycle is longer than this or is variable in length. Shorter cycle length will require an assessment earlier than day 21. Testing for LH is difficult in practice since the day of the LH surge cannot be predicted in advance with certainty. Urinary kits are available to detect LH and can be helpful in treatment cycles where the timing of artificial insemination is critical. Their use in detecting ovulation in routine investigation is not encouraged.

In the absence of any additional clues in history or examination to suggest an endocrine disturbance, assessment of ovulation through progesterone measurement will be sufficient on its own to confirm normal ovulatory function. However, if there is a history of irregular periods or amenorrhoea, especially if associated with galactorrhoea, hirsutism or obesity, additional endocrine investigations will be required. These include the measurement of follicle-stimulating hormone (FSH), LH, thyroid-stimulating hormone and prolactin, timing sampling to coincide with the early follicular phase of the cycle if the woman is having periods. If significant hirsutism or acne is present, the measurement of testosterone, sex-hormone-binding globulin and adrenal androgens, including androstenedione, dehydroepiandrosterone, dehydroepiandrosterone sulphate and 17-hydroxy progesterone (17-OHP), should be performed.

Ultrasound follicle tracking

Ovarian ultrasound to track follicular development, rupture and corpus luteum formation may be useful in ovulation

induction treatment cycles; however, it is time consuming and intrusive, and thus is rarely used in the routine investigation of ovulation. Observation of cysts within the ovary in the luteal phase may be indicative of luteinized unruptured follicles. On occasions, these may be associated with subnormal production of progesterone, so-called 'luteal-phase deficiency'. It is uncertain whether or not these phenomena are important in the genesis of infertility, since luteal cysts and suboptimal progesterone profiles are not seen consistently in tracked cycles in individual patients. However, scanning in the early follicular phase is helpful in assessing ovarian morphology. A diagnosis of polycystic ovaries is made if there are at least 12 follicles of 2–9 mm diameter and/or the ovarian volume is greater than 10 cm³. Assessment of endometrial thickness within the uterus may be a useful indicator of the level of oestrogen exposure in women presenting with amenorrhoea, which can be of assistance in reaching a diagnosis.

Ovulation failure

The World Health Organization (WHO) classification of ovulatory dysfunction (Table 20.3) is a helpful system of categorizing disorders of ovulation based on the pathogenesis of the disorder.

WHO Type I ovulatory dysfunction may be due to a failure of the hypothalamus to produce gonadotrophin-releasing hormone (GnRH) which regulates the production of gonadotrophins by the pituitary gland. Typically, FSH and LH levels are low (<5 IU/l). Oestrogen levels are also low, and an ultrasound scan of the uterus will show a thin or absent endometrial stripe. The patient fails to menstruate after exposure to a short course of progestagen treatment.

A similar situation may arise in cases of hyperprolactinaemia, which may be associated with galactorrhoea as well as amenorrhoea. Normal pulsatile release of GnRH from the hypothalamus is compromised, and follicular growth ceases with resultant amenorrhoea. This may also occur in some instances of hypothyroidism, where high levels of thyrotrophin-releasing hormone can alter dopamine-mediated regulation of the anterior pituitary and cause hyperprolactinaemia. If hyperprolactinaemia is found, magnetic resonance imaging of the pituitary may identify a microadenoma or, occasionally, a larger pituitary tumour. Some drugs that block the effect of dopamine, such as phenothiazines, certain antipsychotics, metoclopramide and others, can cause hyperprolactinaemia.

Acquired GnRH deficiency may also arise in association with weight loss, as seen in anorexia nervosa and in individuals who undertake excessive exercise. Kallman's

syndrome presents as hypothalamic amenorrhoea associated with anosmia, and results from a congenital absence of GnRH-releasing neurones in the hypothalamus. The syndrome is characterized by a lack of gonadotrophin secretion from the anterior pituitary and consequent hypogonadism. Pituitary failure may arise due to necrosis or thrombosis secondary to tumour formation. Rarely, massive obstetric haemorrhage and prolonged hypotension can lead to pituitary infarction (Sheehan's syndrome).

The most common ovulation disturbances (WHO Type II) are associated with disordered hypothalamic–pituitary–ovarian function. These women will have oestrogen levels in the normal range and many are overweight, presenting with infrequent or absent periods. A common finding is the presence of polycystic ovaries on ultrasound, seen in up to 90% of such cases. In contrast to WHO Type I patients, these women will usually menstruate after exposure to a short course of progestagen treatment. Ultrasound scanning should be timed to coincide with either a natural or progestagen-induced menstrual period. Where there is clinical or biochemical evidence of hyperandrogenism, this, together with menstrual irregularity and ovarian morphology, should be taken into account in reaching a diagnosis of polycystic ovary syndrome (PCOS). A consensus view on standardized criteria for the diagnosis of PCOS has helped in establishing a uniform approach, and facilitated easier comparison of clinical and research experience in different centres (Rotterdam ESHRE/ASRM-sponsored PCOS Consensus Workshop Group 2004a,b). It was agreed that the presence of any two of the following triad are sufficient to make the diagnosis: (i) oligo-ovulation and/or anovulation; (ii) polycystic ovaries on ultrasound; and (iii) clinical and/or biochemical hyperandrogenism.

Approximately 10–20% of patients with PCOS have an associated elevation in prolactin, but this is usually mild and not of clinical consequence. On occasions, ovulatory failure may result from 21-hydroxylase deficiency in the adrenal gland leading to elevated serum levels of 17-OHP, an androgenic steroid precursor of cortisol. High androgens disturb normal follicular growth, and patients may present with irregular or absent periods associated with signs of androgen excess including hirsutism, acne and enlargement of the clitoris. Other causes of hyperandrogenism, such as adrenal tumours and Cushing's syndrome, may need to be considered where adrenal androgen levels are found to be high.

Insulin resistance has been well described in women with PCOS, and it has been estimated that they have a three to seven times higher risk of developing type 2 diabetes in later life; regular screening may therefore be appropriate. Amen-

Table 20.3 The World Health Organization classification of ovulatory disorders

Group	Type of Disorder	%	Biochemical Characteristics
I	Hypothalamic pituitary failure (hypothalamic amenorrhoea or hypogonadotrophic hypogonadism)	10	Low basal gonadotrophins, normal prolactin, low oestrogen
II	Hypothalamic pituitary dysfunction	85	Gonadotrophins and oestrogen levels in the normal range
III	Ovarian failure	4–5	High gonadotrophins, low oestrogen

orrhoea in PCOS may also be associated with an increased lifetime risk of endometrial cancer. Progestagen-induced menstruation should thus be facilitated three to four times per year, particularly if increased endometrial thickness is seen on ultrasound.

Ovarian failure

In patients presenting with amenorrhoea and where initial biochemical screening and physical examination lead one to suspect ovarian failure (WHO Type III), the presence of a genetic disorder such as Turner's syndrome (45XO) or Turner mosaic (45XO/46XX) should be considered and a karyotype performed. Occasionally, deletions in one of the X chromosomes or defects in the *fragile X* gene may lead to ovarian failure, but agenesis of the ovaries (associated with primary amenorrhoea) and premature ovarian failure (presenting as secondary amenorrhoea before 40 years of age) is sometimes found in the presence of a normal karyotype. Acquired ovarian failure may occur as a result of previous medical treatment such as chemotherapy or radiotherapy for cancer. Autoimmune ovarian failure should be considered, and screening for antiovarian antibodies may be useful in reaching a diagnosis. If positive, the need to screen for other autoimmune disorders including hypothyroidism, adrenal insufficiency (Addison's disease), diabetes mellitus and pernicious anaemia should be considered (see Chapter 17, Ovulation induction, for more information).

Tubal Factor Infertility

Tubal pathology is a contributory factor in 15–30% of women presenting with infertility. Normal tubal function should permit gamete transport, fertilization and the subsequent passage of the embryo to the uterus such that implantation can take place at the appropriate stage in the menstrual cycle. The most common cause of tubal factor infertility is past pelvic infection through sexually transmitted infection, e.g. *Chlamydia trachomatis*, although previous pregnancy, both successful and failed, or past history of pelvic surgery or endometriosis can be implicated. Occasionally, a Müllerian developmental anomaly may be involved.

The following tests of pelvic anatomy are commonly performed in the diagnostic work-up of women with infertility: (i) X-ray hysterosalpingography (HSG); (ii) laparoscopy; and (iii) hysterosalpingo contrast sonography (HyCoSy).

If the duration of infertility is short (<1 year) and the history and examination findings do not suggest that a tubal factor is likely, examination of the pelvis may be deferred until the duration of infertility approaches 18 months. However, if there is a positive feature in the history, if the pelvic findings on bimanual examination are abnormal or if a screening test for *Chlamydia* is positive, an assessment should be arranged without delay.

X-ray hysterosalpingography

This is an outpatient examination and involves the instillation of either a water- or oil-soluble contrast medium through a cannula attached to the cervix. The fluid, being

Figure 20.1 X-ray hysterosalpingography. This shows a normal uterine outline with passage of dye through tubes of normal calibre and spillage of dye into the pelvis.

radio-opaque, can be visualized under X-ray screening conditions. An assessment is made of the normality of the uterine cavity. Passage of dye to the side of the uterus permits an assessment of tubal anatomy (Figure 20.1). The diameter of the tube should be small through its interstitial, isthmic and ampullary portions, but the diameter increases slightly as the infundibulum is reached. Unimpaired passage of dye throughout the length of the tube and dispersal into the peritoneal cavity is suggestive of normal anatomy. If there is impaired flow or localization of spill distally, one should be suspicious of peritubal adhesions. The finding of a hydrosalpinx will be indicative of severe tubal damage. Sometimes, unilateral or bilateral tubal spasm occurs and a mistaken diagnosis of proximal tubal obstruction is made. An intravenous injection of glucagon can help to relax this, but if the finding persists, a cornual block is a possibility. It is important, particularly in women under 25 years of age, to consider the need for antibiotic prophylaxis since *Chlamydia* infection could be reactivated in susceptible women. Azithromycin or doxycycline is usually used.

HSG should not be carried out if the patient is menstruating. In addition, women should be advised to avoid conception in the cycle in which the procedure is carried out. If unprotected intercourse has occurred, the examination should be deferred.

The contrast medium used in HSG may contain iodine, and the possibility of allergic reactions should be borne in mind. Significant extravasation of oil-soluble contrast media within the pelvis may lead to lipogranuloma formation. There is some evidence that the use of an oil-soluble contrast medium (lipiodol) may enhance the chance of pregnancy in unexplained infertility (Johnson et al 2004), although it has not gained widespread popularity as a therapeutic choice.

Laparoscopy and dye hydrotubation

It is generally accepted that laparoscopy and dye hydrotubation is the gold standard of tubal assessment. In this procedure, which, like HSG, should avoid the time of menstruation

and any chance of pregnancy, a coloured dye is injected through the cervix while carrying out a laparoscopic inspection of the pelvis (Figure 20.2). Failure of dye to pass through the tube is indicative of blockage (Figure 20.3).

Direct visualization of the pelvis permits identification of adhesions, fibroids, endometriosis, ovarian cysts and other pathology which may be relevant to infertility and would be missed at HSG. The likelihood of finding tubal disease is increased if the patient has a positive *Chlamydia* screening test (Coppus et al 2007). Immediate treatment of pathology is also possible at laparoscopy, which may be particularly

relevant where endometriosis is found, provided that appropriate consent has been obtained.

The procedure should be carried out in a systematic fashion and a written record, together with photographs if possible, should be made of the findings. At least two ports are required to allow manipulation of pelvic structures to ensure thorough assessment. The bowel can sometimes obscure the view, and a probe to move this out of the way will often be helpful. Sometimes, a third port may be required if the surgeon wishes to treat minor adhesions or endometriosis, in order to allow the introduction of

Figure 20.2 The technique of laparoscopy. (A) Instrumentation. This shows the uterine body with the right fallopian tube and the ovary. (Bi) Normal pelvis with spillage of dye from the fimbrial end of tube (Bii).

scissors or diathermy/laser instruments and suction/irrigation apparatus.

The use of a diagram, such as that produced by the American Society for Reproductive Medicine (ASRM), to record findings is often helpful in explaining to patients what has been seen and done, as well as providing a formal record of the findings, particularly if endometriosis is found (Figure 20.4).

General anaesthesia carries a small risk of reaction to the drugs used. In addition, the introduction of laparoscopic instruments presents a risk of injury to intra-abdominal structures such as the bowel, bladder and blood vessels. Patients who have undergone previous abdominal surgery, in particular those with a mid-line incision, are particularly at risk. The technique used in the introduction of instruments may need to be adapted to take account of this increased hazard. Alternatively, HSG may be preferred.

Hysterosalpingo contrast sonography

In the last two decades, HyCoSy has attracted some interest as an additional method for assessing tubal patency (Hamilton et al 1998). Carried out as an outpatient or office procedure, a small balloon catheter is inserted into the uterine

cavity through the cervix (Figure 20.5). A vaginal scan is performed while a suspension of an ultrasound contrast agent (Echovist) is injected through the catheter. Usually, only 2–5 ml of fluid will be required. The medium contains galactose granules, and if flow is seen through the length of the tube, it is likely to be patent. Hydrosalpinges can also be identified. Saline alone can be used if inspection of the uterine cavity alone is required, and good imaging of endometrial polyps can be obtained. The technique requires considerable ultrasound skill, and some patients find the instillation of the fluid uncomfortable. There is no evidence of therapeutic benefit through flushing with the medium used in HyCoSy (Lindborg et al 2009).

Hysteroscopy

Hysteroscopic examination of the uterine cavity may be carried out as an outpatient procedure, although if a laparoscopic assessment is being carried out, it is a simple affair to combine the two procedures. Either carbon dioxide or saline/glycine may be used to distend the cavity to permit adequate inspection. Uterine malformations, fibroids, endometrial polyps, adhesions and other conditions may be identified and treated using this technique, although it is controversial whether or not some of these findings contribute to infertility to any great degree.

Evaluation of diagnostic tests of tubal factor infertility

With HSG, one is interested to know whether the test identifies normal and abnormal tubes correctly compared with the gold standard, laparoscopy. The value of a test for tubal blockage (test positive) can therefore be described using a number of statistical descriptors, as shown in Table 20.4.

A meta-analysis evaluating HSG assessment of tubal patency using laparoscopy as the gold standard showed 65% sensitivity and 83% specificity (Swart et al 1995, Mol et al 1996). One can deduce from this that although HSG is of limited value in detecting tubal blockage because of its low sensitivity, its high specificity makes it a better test for identification of tubal patency. The negative predictive value (94%) of the test as a predictor of tubal patency is also high, suggesting that the finding of normal tubes on HSG is likely to be correct. However, a low positive predictive value of

Figure 20.3 A blocked fallopian tube with hydrosalpinx formation. The distal end of the tube has been exposed, revealing terminal clubbing.

Table 20.4 Hysterosalpingography as a diagnostic test of tubal patency: performance vs laparoscopy

Sensitivity	Does the test correctly identify all patients with blocked tubes?	True positives / True positives + false negatives	65%
Specificity	Does the test correctly identify all patients with patent tubes?	True negatives / True negatives + false positives	83%
Positive predictive value	The proportion of patients with positive test results (tubes blocked) who are correctly diagnosed	True positives / True positives + false positives	38%
Negative predictive value	The proportion of patients with negative test results (tubes patent) who are correctly assigned as normal	True negatives / True negatives + false negatives	94%

AMERICAN SOCIETY FOR REPRODUCTIVE MEDICINE REVISED CLASSIFICATION OF ENDOMETRIOSIS

Patient's Name _____ Date _____
 Stage I (Minimal) - 1-5
 Stage II (Mild) - 6-15
 Stage III (Moderate) - 16-40
 Stage IV (Severe) - >40
 Total _____
 Laparoscopy _____ Laparotomy _____ Photography _____
 Recommended Treatment _____
 Prognosis _____

PERITONEUM	ENDOMETRIOSIS	<1cm	1-3cm	>3cm
	Superficial	1	2	4
OVARY	Deep	2	4	6
	R Superficial	1	2	4
	Deep	4	16	20
	L Superficial	1	2	4
POSTERIOR CULDESAC OBLITERATION		Partial	Complete	
		4	40	
OVARY	ADHESIONS	<1/3 Enclosure	1/3-2/3 Enclosure	>2/3 Enclosure
	R Filmy	1	2	4
	Dense	4	8	16
	L Filmy	1	2	4
TUBE	Dense	4	8	16
	R Filmy	1	2	4
	Dense	4*	8*	16
	L Filmy	1	2	4
TUBE	Dense	4*	8*	16

*If the fimbriated end of the fallopian tube is completely enclosed, change the point assignment to 16.

Denote appearance of superficial implant types as red (R), red, red-pink, flamelike, vesicular blobs, clear vesicles), white (W), opacifications, peritoneal defects, yellow-brown), or black (B) black, hemosiderin deposits, blue]. Denote percent of total described as R __%, W __% and B __%. Total should equal 100%.

Additional Endometriosis: _____

Associated Pathology: _____

38% of the test suggests that HSG is not a reliable indicator of tubal occlusion, and in the circumstances of an abnormal HSG result, it would be wise to consider a laparoscopic assessment to confirm or refute the findings (National Collaborating Centre for Women's and Children's Health for the National Institute of Clinical Excellence 2004).

HyCoSy also performs fairly well in detecting normality and hydrosalpinx formation; however, similar to HSG, it is less reliable in identifying tubal blockage (Hamilton et al 1998).

Endoscopic assessment of the tubal lumen to study mucosal appearance has not proved to be helpful in routine work-up of infertility. Falloposcopy achieves access to the tube per vaginam (Rimbach et al 2001). Salpingoscopy can be performed at laparoscopy or laparotomy where the tube is cannulated through the fimbria (de Bruyne et al 1997). Initially thought to be of potential use in selecting patients with healthy tubal epithelium who might be suitable for tubal surgery, neither of the techniques has gained much popularity and they are rarely used.

Endometriosis, Fibroids and Uterine Factors

Endometriosis

Endometriosis is a debilitating condition which has associations with infertility, particularly where there is anatomical distortion of the pelvis. Women who are susceptible to the condition may have genetic, immunological, hormonal or environmental factors contributing to the problem (Crosignani et al 2006). A family history of the condition should alert the gynaecologist to the possibility, particularly if the common symptoms of dysmenorrhoea and chronic pelvic pain are present. Pelvic examination may reveal a fixed, tender retroverted uterus, and on occasions, there may be endometriotic nodules presenting the vault of the vagina or the rectovaginal septum. A combined rectal and vaginal examination may be helpful if this is suspected. Laparoscopic visualization of endometriotic lesions is the cornerstone of diagnosis, although a histological confirmation of an excised lesion is strictly necessary to be absolutely certain.

The accuracy of the diagnosis therefore depends on the degree of skill and vigilance of the surgeon. If endometriosis is found at laparoscopy, it is helpful to stage the disease by reference to the ASRM guidelines (American Society for Reproductive Medicine 1996). There is some evidence that women with mild endometriosis have reduced fertility (Akande et al 2004), and that treatment, such as with diathermy, may improve the natural chances of conception in minimal/mild disease (Marcoux et al 1997). A suspicion of endometriosis may be raised if vaginal ultrasound examination of the pelvis is painful, or if a cyst with a hazy 'ground glass' appearance is seen in the ovary, suggestive of an endometrioma. Magnetic resonance imaging of the uterus may be helpful if one suspects adenomyosis. Biochemical assay of CA125, if raised, may be suggestive of endometriosis, although this is non-specific. Women with Müllerian abnormalities promoting retrograde menstruation are at greater risk of developing endometriosis.

Fibroids

Fibroids are among the most common benign tumours in women, with a reported prevalence of 3–8% in unselected women of reproductive age (Borgfeldt and Andolf 2000), although they occur with higher frequency in older women and in certain ethnic populations. Fibroids are often asymptomatic but an association with infertility is possible (Somigliana et al 2007), particularly where the tumour impinges on the cavity of the uterus (Khalaf et al 2006, Klatsky et al 2007). Abdominal palpation and vaginal examination may reveal a mass arising from the pelvis. Ultrasound examination is usually performed to confirm the diagnosis, and this has high sensitivity and specificity as a test. If the relationship between the fibroid and the uterine cavity is unclear from an initial ultrasound assessment, HyCoSy or HSG may be useful to distinguish submucosal from intramural lesions. Hysteroscopic evaluation of the degree of myometrial penetration by the fibroid is essential if surgical excision is contemplated (Di Spiezio Sardo et al 2008). Discrimination between adenomyosis and fibroids may be facilitated with the use of ultrasound where the absence of a tumour capsule and lacunae within the lesion may be suggestive of the former. Magnetic resonance imaging can also be of help.

Potential endometrial abnormalities

Undiagnosed uterine pathology as a cause of infertility, recurrent implantation failure (RIF) or recurrent miscarriage is an attractive concept. However, the evidence that disturbed endometrial receptivity is important in infertility is mixed. Endometrial assessment by timed sampling and histological dating is the most described method of assessing the normality of endometrial development. It is dependent on accurate timing of sampling endometrium relevant to the LH surge (Li et al 2002), and has been largely abandoned in routine practice, as has the concept of luteal-phase deficiency as a major cause of infertility. Ultrasound-measured endometrial thickness is a poor predictor of implantation potential in in-vitro fertilization (IVF) (Margalioth et al 2006), particularly where high-quality embryos are available. Disturbances in cytokine expression and action have

been postulated as a cause of RIF, but analysis of these factors remains a research tool rather than a clinical tool. The role of immunological causes and thrombophilia in infertility is also uncertain. Some early studies suggested an association between antiphospholipid syndrome and RIF, but this has not been confirmed in larger prospective studies. The role of natural killer cells in RIF is disputed (Rai et al 2005). For the moment, there is no convincing evidence for an association. An association between hereditary thrombophilia and RIF has also been described in some, but not all, studies, and screening for these disorders is still controversial (see Chapter 23, Sporadic and recurrent miscarriage, for more information).

Unexplained Infertility

Despite the use of investigation pathways as outlined above, it is debatable whether or not the basic tests of semen quality, ovulation and tubal patency are in any way accurate in predicting live birth (Taylor and Collins 1992). From the above discussion, it will also be clear that there is an ongoing, and relevant, debate concerning the existence of subtle disturbances in reproductive function in the female and their impact on fertility. While endometrial function is undoubtedly important in the genesis of conception, a number of other elements in the path to establishment of pregnancy have been considered as causes of infertility. Few are amenable to simple investigation. Possibilities are listed in Table 20.5.

Postcoital testing

An area of considerable interest over many years has been the assessment of sperm–cervical mucus interaction through the postcoital test (PCT). As the time of ovulation nears, cervical mucus secretion, under the influence of oestradiol, changes in quantity. After intercourse, sperm should swim freely within the mucus and transportation of sperm to the upper genital tract can take place. Cervical mucus–sperm hostility as a cause of infertility continues to be debated due to the methodological issues of concern in its use. The test is intrusive in so far as the couple are asked to have intercourse at a prescribed time, and then the female attends the clinic for a sample of mucus to be obtained from the cervix. The investigator examines the specimen to determine if there are motile sperm visible under light microscopy. In theory, the test could give an indication that intercourse has taken place, that timing is correct, that the mucus is receptive, and that sperm numbers and motility are adequate. In critically evaluating the usefulness of the PCT in clinical practice, many would argue that it lacks predictive power in its ability to identify those who will conceive naturally from those who will not (Oei et al 1995). Furthermore, there is no standardization of the methodology of the test; for example, timing of intercourse in relation to ovulation, timing of examination of sampled mucus relative to intercourse, and 'normal' sperm numbers and motility levels within examined mucus (Evers 2002). One study (Glazener et al 2000) found the PCT to be useful in predicting spontaneous conception in couples with otherwise unexplained infertility of a short duration (<3 years).

Table 20.5 Putative causes of unexplained infertility

Endocrine factors
Abnormal follicle growth
Suboptimal progesterone secretion (luteal-phase deficiency)
Luteinized unruptured follicle syndrome
Hypersecretion of luteinizing hormone
Ovulatory hyperprolactinaemia
Ovarian factors
Zona pellucida antibodies
Diminished ovarian reserve (ovarian ageing)
Uterine/endometrial factors
Congenital uterine abnormalities
Submucous fibroids
Abnormal uterine perfusion
Altered cytokine expression and action
Disturbed T-cell and natural killer cell function
Tubal factors
Disturbed tubal function, i.e. peristalsis, cilia
Suboptimal metabolic support of gametes and embryos
Altered immune activity
Peritoneal factors
Mild endometriosis
Occult infection
Altered immune activity
Genetic factors
Gamete and embryo aneuploidy
Poor embryo morphology, cleavage and blastocyst formation
Sperm–cervical mucus interaction
Altered cervical mucus production
Antisperm antibodies
Psychogenic factors
Inadequate coital function

However, a study which examined whether or not intra-uterine insemination improved the chance of conception, where a PCT was negative, only showed a marginal effect (Mol 2001).

Diagnostic category

Unexplained infertility presents a frustrating diagnosis for both clinician and patient. The range and accuracy of the tests which are used to investigate the infertile will influence the chance of a 'diagnostic label' being attached to the problem (Gleicher and Barad 2006). Whether such a label leads to help in forming a prognosis or formulating a treatment plan is debatable (Siristatidis and Bhattacharya 2007). In some instances, the finding of 'abnormality' occurs with similar frequency in both those who ultimately conceive naturally and those who remain infertile (Guzick et al 1994). In recent times, the age profile of patients attending fertility clinics has changed, with many women delaying childbearing for a variety of reasons. For many, age alone is a major

factor in determining prognosis, and age may also influence the probability of a diagnosis of unexplained infertility being made. It has been estimated that the chance of reaching a diagnosis of unexplained infertility is doubled if the female is over 35 years of age compared with females under 30 years of age (Maheshwari et al 2008). As discussed below, diminished ovarian reserve may, in theory, be a missed cause of infertility in otherwise unexplained infertility. For most clinics, female age, together with parity and the duration of infertility, are the three factors with the greatest bearing on prognosis.

Insights from Assisted Conception

The assisted conception population will usually include those who have prolonged infertility and, as such, is arguably not truly representative of the general infertility population. However, outcomes in those who access IVF treatment, although under very different conditions, may give some insight into what may be occurring in natural attempts to conceive, and afford help to couples in coming to terms with their infertility. Occasionally, poor fertilization outcomes may unmask functional problems regarding sperm or egg quality. Failed fertilization may be due to hardening of the zona pellucida, associated with ageing of the oocyte. Embryo quality, as judged by morphology and cleavage patterns, may be consistently suboptimal. The association with such findings and aneuploidy in embryos is well established. Women who fail to respond well to ovarian stimulation may have a qualitative or quantitative disturbance in follicular physiology. Tests of ovarian reserve to predict outcome have been widely used in those who are embarking on IVF treatment. Early-follicular-phase FSH, anti-Müllerian hormone, inhibin-B and ovarian-ultrasound-observed antral follicle count are the most popular measures. Dynamic tests of ovarian reserve have also been described using clomiphene or exogenous gonadotrophin stimulation. However, the predictive power of all these tests, relevant to a number of endpoints including eggs retrieved and clinical pregnancy, is poor, except at the extremes of ranges. For the moment, they should be regarded as unsuitable for routine evaluation of the infertile female (Maheshwari et al 2008).

Conclusions

Infertility is a major public health problem, causing significant distress to those directly involved, as well as family and friends. It is essential that the limited public resources are used prudently to maximize the quality of care provided. The preliminary assessment of the availability of eggs and sperm, together with a determination that the gametes can meet, should provide a diagnosis for the majority of couples. It should be possible to provide a prognosis, usually favourable, and where necessary, treatment can be initiated within a relatively short time. The importance of efficient mechanisms of referral and investigation cannot be overestimated. Regional integration of services, from GP to tertiary-level hospital settings, should be established to minimize delay for patients and avoid unnecessary repetition of investigations.

KEY POINTS

1. The chance of pregnancy in a normal fertile population is 85% after 1 year of unprotected intercourse and 92% after 2 years.
2. Couples should only be referred after 1 year of trying unless there is an obvious risk factor for infertility.
3. Irregular cycles are suggestive of ovulatory dysfunction—polycystic ovarian syndrome is the most common cause.
4. Serum progesterone levels >30 nmol/l in the putative luteal phase of the cycle are indicative of ovulation.
5. If ovarian failure is diagnosed a karyotype should be performed—Turner's syndrome (45XO) may be found. An association with *Fragile x* gene is possible.
6. If autoimmune ovarian failure is diagnosed screening for other autoimmune disorders should be recommended.
7. Unless there is a strong suspicion of pelvic pathology a hysterosalpingogram is a reasonable first line test of tubal factor infertility.
8. Laparoscopy during the diagnostic workup permits assessment and treatment of simple pathology e.g. mild endometriosis and should be offered if pelvic pathology is suspected from the history or examination findings.
9. Fibroids may be associated with infertility if the cavity of the uterus is distorted. Hysteroscopy or hydrosalpingography are useful ancillary investigations if uterine abnormality is suspected.
10. The post coital test is of doubtful value as a routine test in the evaluation of infertility.
11. The role of immune factors in implantation failure is uncertain.
12. IVF may provide insight in to factors associated with infertility and be of help to couples in coming to terms with their situation.

HORMONAL CONTROL OF SPERMATOGENESIS	294	CHANGES IN MALE REPRODUCTIVE HEALTH	309
MALE INFERTILITY	297	KEY POINTS	310

Introduction

There has been rapid progress during the past 20 years in our understanding of male reproductive physiology, with wide-ranging contributions from cell and molecular biologists, urologists and endocrinologists, whose efforts have contributed to establishing the discipline of andrology. However, this specialty is not established in the UK, and men with reproductive disorders often present to the gynaecologist through the intermediary of their female partners. It is therefore important for gynaecologists to have some knowledge of male reproductive function and its disorders in order to recognize potential problems, as well as an understanding of the available diagnostic techniques and treatment options.

This chapter aims to provide the practising gynaecologist with an overview of clinical andrology with an emphasis on male infertility. A description of normal physiology is given as the foundation for explaining pathophysiological mechanisms and as a basis for formulating rational treatment where possible.

Physiology

The testis can be thought of as having two major interconnected functions in the adult: the production of testosterone, which maintains a wide range of physiological processes; and the production of spermatozoa and thereby fertility.

Spermatogenesis

Spermatogenesis takes place in several hundred tightly coiled seminiferous tubules arranged in lobules (Figure 21.1) (Dym 1977), which constitute some 80% of testicular volume in man. Testis volume therefore reflects spermatogenesis more than testosterone production. Each tubule resembles a loop draining at both ends into a network of tubules, the rete testis, and thence into the epididymis, a single but highly coiled tube which, in turn, drains into the unconvoluted and muscular-walled vas deferens.

The walls of the seminiferous tubules are composed of germ cells and Sertoli cells around a central lumen, surrounded by peritubular myoid cells and a basement membrane (Figure 21.2). Spermatogenesis is a continuous sequence of closely regulated events, highly organized in space and time, whereby cohorts of undifferentiated diploid germ cells (spermatogonia) multiply and, while maintaining the population of stem cell spermatogonia, are then transformed into haploid spermatozoa. The following events can be observed in the seminiferous epithelium during normal spermatogenesis.

- Mitotic division (at least four) of stem cells to form cohorts of spermatogonia which, at intervals of 16 days, differentiate into primary preleptotene spermatocytes to initiate meiosis.
- Meiotic reduction divisions of spermatocytes to form round spermatids.
- Continuous remodelling of Sertoli cells in order to direct the migration of germ cells from basal to luminal positions.
- Transformation (spermiogenesis) of large spherical spermatids into compact, virtually cytoplasm-free spermatozoa with condensed DNA in the head crowned by an apical acrosomal cap, and a tail capable of propulsive beating movements.
- Spermiation, whereby the spermatozoa are released from the Sertoli cell cytoplasm into the tubular lumen.

Cohorts of undifferentiated germ cells, joined to each other by cytoplasmic bridges, progress through these different steps in synchrony so that several generations of developing germ cells are usually observed at any one part of the seminiferous epithelium at any one time. The total time taken for a cohort of spermatogonia to develop into spermatozoa is 74 days, during which time at least three further generations of spermatogonia have also successively, at intervals of 16 days, initiated their development. In the human, spermatogenesis is arranged in a helical manner, so that cross-sections show more than one stage of spermatogenesis within individual seminiferous tubules. This

Figure 21.1 Human testis, epididymis and vas deferens showing efferent ducts leading from the rete testis to the caput epididymis and the cauda epididymis, continuing to become the vas deferens.

organizational arrangement differs from that in many other species (e.g. rodents), in which spermatogenesis is arranged longitudinally and thus only one stage of spermatogenesis is seen in a cross-section of a tubule.

Sertoli cell function

Sertoli cells have extensive cytoplasm which spans the full height of the seminiferous epithelium from basement membrane to lumen (Figure 21.2). Where adjacent Sertoli cells come into contact with each other near the basement membrane, special occluding junctions are formed which divide the seminiferous epithelium into a basal (outer) compartment, which interacts with the systemic circulation, and an adluminal (inner) compartment enclosed by a functional permeability barrier, the blood–testis barrier (Figure 21.2). Spermatogonia divide by mitosis in the basal compartment, while the two reduction divisions of the spermatocytes and spermiogenesis are confined to the avascular microenvironment of the adluminal compartment created by the blood–testis barrier. The developing germ cells are therefore completely dependent on Sertoli cells for metabolic support. In response to appropriate trophic stimuli [of which follicle-stimulating hormone (FSH) and testosterone are the best described], Sertoli cells secrete a wide range of substances including growth factors and a distinctive tubular fluid high in potassium and low in protein which bathes the mature spermatozoa.

Sertoli cells contribute directly to the feedback regulation of pituitary gonadotrophin secretion. The existence of an endocrine product of the testis termed ‘inhibin’ was postulated for many decades. Inhibin B is a dimeric glycoprotein secreted by Sertoli cells which has a physiological role in the

Figure 21.2 Diagrammatic representation of the anatomical and functional relationship between germ cells, Sertoli cells and Leydig cells. Note the division of the seminiferous epithelium into adluminal and basal compartments by the tight junctions between adjacent Sertoli cells and the bidirectional secretion of Sertoli cell products (e.g. inhibin) into the lumen and interstitial space. ABP-T, androgen-binding protein; testosterone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; T, testosterone.

regulation of FSH secretion. Inhibin B concentrations reflect the functional activity of the seminiferous tubule and show a positive relationship with sperm production. Its production requires and reflects the interaction of the germ cell population with the Sertoli cells, and is absent in men with Sertoli cell only syndrome. The measurement of inhibin B may be of clinical value as a marker of the activity of the seminiferous epithelium (O'Connor and De Kretser 2004). Inhibin A, the product of the dominant follicle and the corpus luteum in women, is not present in the circulation in men.

Unlike the actively dividing germ cells, Sertoli cells do not proliferate in the adult testis. Spermatogenesis is a cyclical process which is critically dependent on changes in Sertoli cell function associated with the constantly changing combination of germ cells in contact with its cytoplasm. Changes in the germ cell complement in contact with any one Sertoli cell occur at a fixed sequence and interval. Thus, the synchronization of these repetitive cyclical changes in Sertoli cell function, associated with the variations in germ cell metabolic requirements as they divide and differentiate, has now become one of the central tenets of our conceptualization of normal spermatogenesis (Sharpe 1990). Although pituitary gonadotrophins provide obligatory trophic support for testicular function as a whole, the classic concept that luteinizing hormone (LH) stimulates Leydig cell steroidogenesis and FSH controls functions in the seminiferous tubules is far too simplistic in the light of our current understanding of spermatogenesis. There is now good evidence that the interstitial and tubular compartments are not functionally distinct, but that there is a close and complex interrelationship between them. Thus, testosterone from the interstitial Leydig cells stimulates Sertoli cell functions either directly or via the peritubular cells, as does Leydig-cell-derived insulin-like factor 3, itself critical for testicular descent (Ivell et al 2005). Altered tubular/Sertoli cell function, on the other hand, can induce changes in Leydig cell

steroidogenesis, although the identity of the intercompartmental regulator(s) is unknown.

Testosterone is the only and probably the most important paracrine hormone clearly identified, and its presence in sufficient concentrations in the seminiferous tubules is an absolute requirement for spermatogenesis. How much testosterone is required and how it exerts its effects are just some of the fundamental questions that are still unanswered. Despite the large gaps in our existing knowledge, it is becoming increasingly accepted that local coordination of the multifarious functions in a variety of different cell types within the testis, orchestrated by the diverse functional capabilities of the Sertoli cells, holds the key to quantitatively normal spermatogenesis.

The Leydig cell

The adult human testis contains some 500 million Leydig cells clustered in the interstitial spaces adjacent to the seminiferous tubules. The biosynthesis of testosterone in Leydig cells is under the control of LH which binds to specific surface membrane receptors. Steroidogenesis is stimulated through a cyclic adenosine monophosphate (cAMP)–protein kinase C mechanism which mobilizes cholesterol substrate and promotes the conversion of cholesterol to pregnenolone by splitting the C21 side chain. The subsequent steps in the biosynthetic pathway involve the weakly androgenic intermediates dehydroepiandrosterone and androstenedione before testosterone, the principal secretory product, is obtained. Testosterone is secreted into the spermatogenic venous system, testicular lymphatics and tubular fluid.

Testosterone is the most important circulating androgen in the adult male, since most dihydrotestosterone is formed locally in androgen-responsive target tissues. When circulating in plasma, testosterone is bound to sex-hormone-binding globulin (SHBG) and albumin. The latter binds to all steroids with low affinity, while SHBG, a glycoprotein synthesized in the liver, has a high affinity but a low capacity for testosterone. In men, 60% of circulating testosterone is bound to SHBG, 38% is bound to albumin and 2% is free. Free and albumin-bound testosterone constitute the bioavailable fractions of circulating testosterone, but recent evidence suggests that SHBG-bound testosterone may also be extractable in some tissues, although the functional significance of this is unclear. The plasma concentration of SHBG is regulated by factors including steroid hormones, its synthesis being increased by oestrogens and reduced by testosterone. It is also related to body weight, being lower in the obese. These relationships are the same as in women.

Hormonal Control of Spermatogenesis

The hormonal control of spermatogenesis requires the actions of the pituitary gonadotrophins LH and FSH. There is general agreement that both LH and FSH are needed for the initiation of spermatogenesis during puberty. However, the specific roles and relative contributions of the two gonadotrophins in maintaining spermatogenesis are unclear (Liu et al 2002).

LH stimulates Leydig cell steroidogenesis, resulting in increased production of testosterone. Normal spermatogenesis is absolutely dependent on testosterone. Specific androgen receptors have not been demonstrated in germ cells, but are present in Sertoli and peritubular cells. This indicates that the actions of androgens in spermatogenesis are mediated by the somatic cells of the seminiferous tubules. The concentration of testosterone in the testis is 50 times higher than that in the peripheral circulation. There is thus an apparent gross overabundance of testosterone within the normal adult testis, the significance of which is uncertain. It is possible that some androgen-mediated functions in the testis are not mediated by classic androgen receptors. Steroids other than testosterone may also have important roles in the regulation of steroidogenesis. In particular, oestrogen receptors are widely distributed in the male reproductive tract, including the presence of oestrogen receptor β .

FSH initiates function in immature Sertoli cells, prior to the onset of spermatogenesis, by stimulating the formation of the blood–testis barrier and the secretion of tubular fluid and other specific secretory products via FSH receptors which activate intracellular cAMP. Once spermatogenesis is established in the adult testis, Sertoli cells become less responsive to FSH. Evidence for the non-essential role of FSH is provided by individuals with inactivating mutations of the FSH receptor. Such men have been documented to have complete spermatogenesis but with low sperm concentrations (Tapanainen et al 1997). However, it can be shown, in animals immunized against FSH and in experimentally induced hypogonadotrophic men given gonadotrophin replacement, that both testosterone (depending on LH) and FSH are required for quantitatively normal spermatogenesis in the adult (testosterone-replete) testis by determining the number of spermatogonia available by meiosis. However, testosterone on its own can maintain qualitatively normal spermatogenesis once it has been initiated (Matsumoto et al 1984). FSH therefore acts either by increasing spermatogonial mitosis or by decreasing the number of cells that degenerate at each cell division. Testosterone is essential for the subsequent stages from meiosis to spermiogenesis.

Hypothalamic–pituitary–testicular axis

The secretion of gonadotrophins from the anterior pituitary gland is controlled by gonadotrophin-releasing hormone (GnRH) released into the pituitary portal circulation from axon terminals in the hypothalamic median eminence. These neurosecretory neurones in the medial basal hypothalamus are responsive to a wide variety of sensory inputs as well as to gonadal negative feedback. GnRH stimulates the secretion of both LH and FSH. In the adult male, GnRH is released episodically into the pituitary portal circulation at a frequency of approximately every 140 min; each volley of GnRH elicits an immediate release of LH, producing the typical pulsatile pattern of LH in the systemic circulation (Figure 21.3; Wu et al 1989). Although also secreted episodically, FSH and testosterone pulses are not apparent in normal men because of the slower secretion of newly synthesized rather than stored hormone and the longer circulating half-lives. The intermittent mode of GnRH stimulation, within a narrow physiological range of frequency, is obligatory for sustaining the normal pattern of gonadotrophin secretion.

Figure 21.3 (A) Functional relationships in the hypothalamic–pituitary–testicular axis. Gonadotrophin-releasing hormone (GnRH) is secreted into the hypophyseal circulation in an episodic manner, represented by a luteinizing hormone (LH) pulse in the peripheral circulation. (B) Peripheral blood LH concentration sampled in an adult male at 10-min intervals for 24 h from 0900 to 0900 h.

Continuous or high-frequency GnRH stimulation paradoxically desensitizes the pituitary gonadotrophin response in men as in women, because of depletion of receptors and refractoriness of postreceptor response mechanisms. It has recently been demonstrated that the secretion of GnRH is dependent on the newly-described kisspeptin (also known as ‘metastin’). Mutations of the kisspeptin receptor result in pubertal failure. Kisspeptin-containing neurones impinge directly on GnRH neurones in the hypothalamus, and there is emerging evidence that they also mediate effects of metabolic signals such as leptin on the reproductive axis (Seminara and Crowley 2008).

Testosterone exerts the major negative feedback action on gonadotrophin secretion. Its effect is predominantly to restrict the frequency of GnRH pulses from the hypothalamus to within the physiological range. Testosterone also acts on the pituitary to reduce the amplitude of the LH response to GnRH. It is now recognized that these inhibitory effects on GnRH and gonadotrophin secretion are, in part, mediated following conversion of testosterone to oestradiol by the enzyme P450 aromatase. This is demonstrated both by administration of aromatase inhibitors to normal men and by the finding that men with either mutant, non-functional oestrogen receptors or absent aromatase activity have markedly elevated gonadotrophin concentrations despite high-normal testosterone concentrations (Smith et al 1994, Morishima et al 1995). Interestingly, these men also showed marked osteoporosis, suggesting a distinct role for oestrogen in bone. Feedback inhibition of pituitary FSH synthesis is predominantly mediated by inhibin B and also by testoster-

one, particularly at high concentrations. The regulation of FSH secretion by inhibin in addition to testosterone results in the selective rise in FSH but not LH concentrations in men with various disorders of spermatogenesis.

The spermatozoon

The primary function of the spermatozoon is the delivery of a male pronucleus to the fertilized egg. The spermatozoon must conserve its DNA and transport it to the site of fertilization, where it must recognize and fuse with a receptive egg. The ejaculated spermatozoon must first escape from the seminal plasma in which it is deposited beside the cervix, and penetrate the barrier presented by cervical mucus. It must then travel through the uterus to the site of fertilization in the fallopian tube. During this journey, it must complete the process of functional maturation known as ‘capacitation’, an ordered series of events involving reorganization of cell surface components and changes in cellular metabolism and motility patterns, which are a prerequisite for successful fertilization. Having reached the oviduct, the male gamete must recognize the oocyte, penetrate the cumulus oophorus and bind to the zona pellucida. At this point, it must display a unique pattern of movement known as ‘hyperactivated motility’ and undergo the acrosome reaction. This process is initiated by a specific protein component of the zona pellucida (ZP3) and results in release of the contents of the acrosomal matrix, which include the serine protease acrosin and other hydrolytic enzymes including hyaluronidase. In addition, the acrosome reaction results in the generation of a fusogenic equatorial segment, which is the zone of fusion with the oocyte plasma membrane. For a review of sperm structure and function, the reader is referred to Grudzinskas (1995).

To enable it to undertake these complex functions, the human spermatozoon has developed a highly specialized morphology, with its various structural components tailored to specific functional attributes. The appearance of the spermatozoon was first described over 300 years ago by Anthony van Leeuwenhoek. In outline, the spermatozoon has a dense oval head capped by an acrosome and is propelled by a motile tail (Figure 21.4; Fawcett 1975). The head is made up largely of highly condensed nuclear chromatin constituting the haploid chromosome complement, complexed with highly basic proteins termed ‘protamines’. It is covered in its anterior half by the acrosome, a membrane-enclosed sac of enzymes including acrosin and hyaluronidase. The area of the sperm head immediately behind the acrosome (the equatorial region) is important as it is this part which attaches to and fuses with the egg. The shape of the human sperm head is highly pleomorphic, making the morphological definition of a normal sperm head extremely challenging. Behind the head may be found a cytoplasmic droplet which consists of the remains of the residual cytoplasm left after the morphological remodelling of the cell during spermiogenesis.

The tail of flagellum is usually further divided into the midpiece, principal piece and terminal piece, joined to the head by the connecting piece. The motor apparatus of the tail is the axoneme which consists of a central pair (doublets) of microtubules of non-contractile tubulin protein enclosed in a sheath linked radially to nine outer pairs of

Figure 21.4 The internal structure of a spermatozoon with the cell membrane removed.

From Fawcett DW, *The mammalian spermatozoon*. Dev Biol; 44: 394–436, 1975; with permission of Elsevier.

microtubules. The axonemal complex is surrounded by columns of outer dense fibres, which are, in turn, covered by a helix of mitochondria in the midpiece and a fibrous sheath in the principal piece. The dense fibres and the fibrous sheath form the cytoskeleton of the flagellum. Through the hydrolysis of adenosine triphosphate, the dynein arms undergo a series of conformational changes resulting in adjacent doublets sliding over one another. Synchronized movement of groups of microtubules propagating waves of bending motions of the tail is the key to the various modes of coordinated sperm motility. Energy for sperm motility is provided by the sheath of mitochondria in the midpiece of the tail through a second messenger system, involving the calcium-mediated calmodulin-dependent conversion of adenosine triphosphate to cAMP and interaction with the adenosine triphosphatase of the dynein.

Sperm transport and maturation

Spermatozoa within the testis and male tract are quiescent and play little active role in their own transport along the tract. Moreover, they are functionally immature and the maturation process continues as they pass through the epididymis. Passage out of the seminiferous tubules and through the main testicular collecting duct, the rete testis, is due to the flow of secretions from Sertoli cells and rete epithelium and to the intrinsic smooth muscle contractions of the tubules. From the rete, the cells pass through the efferent ducts to the epididymis, a 3–4-m-long single coiled tube whose function is under androgen and neural (adrenergic)

control. It is typically subdivided into a caput or head region, a middle body or corpus, and a distal tail or cauda region which leads into the proximal vas deferens. The epididymal epithelium actively reabsorbs testicular fluid but also secretes a hyperosmolar fluid rich in glycerophosphorylcholine inositol and carnitine. The specific transport of these compounds across the epithelium creates a favourable fluid environment where progressive motility and fertilizing capacity of the spermatozoa are normally acquired. Some of these maturational changes are probably 'housekeeping' functions to ensure that the cell remains viable during its stay in the excurrent ducts, while others are associated with the development of fertilizing ability. In many animal species, spermatozoa retain fertility for several weeks in the cauda epididymis, which acts as a sperm reservoir prior to ejaculation. The human cauda epididymis, in contrast, has a relatively poor storage function, which diminishes further along the vas.

At ejaculation, spermatozoa pass along the vas and are mixed with the secretions of the accessory glands which form over 90% of the volume of the ejaculate. The seminal vesicles contribute the largest volume of alkaline fluid to the ejaculate, and are also the source of seminal fructose, prostaglandins and coagulating proteins. Prostatic secretions contain proteolytic enzymes (which normally liquefy the coagulated proteins in semen within 20–30 min) and are rich in citric acid and zinc. Seminal plasma provides a support medium for transporting male gametes out of the body and for buffering the acidic pH of the vagina, so that a reservoir of functional sperm can be established after ejaculation. Just as testicular germ cells are subjected to constant attrition, ejaculated spermatozoa have to traverse the cervix, uterus and uterotubal junction before reaching the middle third of the oviduct, the site of fertilization. At each barrier, the sperm population is further reduced so that eventually only 200 or so of the most robust spermatozoa have the opportunity to fertilize the ovum. The number of functionally competent sperm is more important than the total number ejaculated.

The cervical canal is the first selective filtering barrier to meet the ejaculated sperm (Figure 21.5). This barrier is virtually complete except during midcycle, when oestrogenized cervical mucus glycoprotein fibrils form parallel chains called 'micelles' which permit spermatozoa with active progressive motility to swim through at a rate of 2–3 mm/min. Spermatozoa probably enter the uterine cavity from the internal os by virtue of their own motility, and appear in the uterine cavity approximately 90 min after insemination. The uterotubal junction is the second of the major physical barriers for spermatozoa. The mechanism for selectivity is not clear, but may depend on factors other than sperm motility since inert particles can pass through. Once the uterotubal junction has been successfully negotiated, a minority of sperm immediately traverse the oviduct to the ampulla; however, the majority congregate in the isthmus until ovulation has occurred. At this time, capacitated sperm showing hyperactivated movements of the tail gradually progress towards the fimbriated end, helped on by the muscular contraction of the oviduct wall and the flow of fluid in the oviduct. A maximum number of spermatozoa is present in the cervix 15–20 min following insemination and remains constant for 24 h, although a rapid decline has commenced

Figure 21.5 Attributes of sperm function associated with fertility *in vivo*. The spermatozoon must escape from seminal plasma, penetrate and traverse the cervical mucus barrier, reach the site of fertilization, undergo capacitation, bind to and penetrate the zona pellucida, fuse with the plasma membrane of the egg, and undergo nuclear decondensation within the cytoplasm of the oocyte.

by 48 h. Some spermatozoa may remain motile at the site of fertilization for up to 3 days (Mortimer 1995).

Male reproductive ageing

Reproductive ageing in the male is not accompanied by such an overt and abrupt fall in gonadal function as occurs in women, but by a more gradual decline. These differences reflect the consequence of a finite pool of gametes compared with one that continually replicates from a stock of stem cells, and the clearer distinction between the endocrine and gametogenic functions of the gonads.

The decline in function of the endocrine output of the hypothalamo–pituitary–testicular axis with age is well established and results in a fall of approximately 50% in plasma testosterone concentrations (Vermeulen 1991). This has both central and peripheral components; thus, there is a relatively small increase in LH. The ‘andropause’ is increasingly the subject of investigation (Wu 2007), with large placebo-controlled studies of the effect of replacement under way. Changes in Sertoli cell function and spermatogenesis with ageing have received more limited investigation, but the data do suggest that there is indeed an age-related decline in function. Spermatogenesis, however, may be well maintained in elderly men.

Male Infertility

Definition and epidemiology

Infertility is commonly defined as the failure of conception after at least 12 months of unprotected intercourse (Rowe 1993), but such a definition serves to obscure the true complexity of the clinical situation. In reality, those couples who fail to achieve a pregnancy within 12–24 months include those who can be considered sterile (i.e. who will never achieve a spontaneous pregnancy) and those who are more properly termed ‘subfertile’ and who have reduced fecundability (probability of achieving a pregnancy within one menstrual cycle) and hence a prolonged time to pregnancy. Accurate assessment of the prevalence of infertility has

always been difficult because of the scarcity of large-scale, population-based studies. Estimates suggest that some 14–17% of couples may be affected at some time in their reproductive lives (Hull et al 1985), with European data suggesting that as many as one in four couples who try may experience difficulties in conceiving (Schmidt 2006).

While infertility is relatively common, it is very difficult indeed to establish the relative contribution of the male partner, given the profound difficulties which exist in the accurate diagnosis of male infertility. Most studies which have attempted to evaluate the aetiology of infertility have used the conventional criteria of semen quality, promulgated by the World Health Organization (WHO) (World Health Organization 1999), to define the ‘male factor’. Although of great importance and shortly to be updated, these criteria are of limited diagnostic value, and a significant proportion of men with normal conventional criteria of semen quality will be infertile because of defects in sperm function, while a significant number of men with abnormal semen quality will have normal sperm function. Very few studies on the epidemiology of male infertility have used functional, as opposed to descriptive, diagnostic criteria. Nevertheless, one common theme to emerge is that, using the available diagnostic techniques, male factor infertility is, in many studies, the most common single diagnostic category.

Pathophysiology

In the simplest terms, male infertility is a failure to fertilize the normal ovum arising from a deficiency of functionally competent sperm at the site of fertilization. Since less than 0.1% of ejaculated sperm actually reach the fallopian tube, it is defective sperm function rather than inadequate numbers of sperm ejaculated that constitutes the most important pathophysiological mechanism in male infertility. Specific lesions leading to defective sperm motility or transport and abnormal sperm–egg interaction are probably the key factors responsible for loss of fertilizing capacity in the gametes. In most instances, however, inadequate sperm function is usually but not invariably accompanied by reduced sperm production, suggesting that specific defects in spermatozoa commonly arise from disturbances in regu-

latory mechanisms which interfere with both germ cell multiplication and maturation in the seminiferous tubules. There is rarely any clinical evidence of systemic endocrine deficiency in men with male infertility. By inference, therefore, disturbances in paracrine regulation within the testis could lead to low sperm output (oligozoospermia), from an increased rate of degeneration in the differentiating spermatogonia at successive mitotic divisions, as well as abnormal spermiogenesis giving rise to spermatozoa with poor motility (asthenozoospermia) and/or abnormal morphology (teratozoospermia). Abnormal epididymal function may lead to defective sperm maturation, impairment of sperm transport or even cell death. Interruption of the transport of normal sperm may be due to mechanical barriers between the epididymis and fallopian tube or abnormal coitus and/or ejaculation.

Aetiology

Notwithstanding the difficulties in diagnosis outlined above, WHO has proposed a scheme for the diagnostic classification of the male partner of the infertile couple (Rowe 1993) (Box 21.1). This approach is of enormous value as a basis for standardization and for comparative multicentre studies. However, many of the male diagnostic categories are of a

descriptive nature (e.g. idiopathic oligozoospermia) or of controversial clinical relevance (e.g. male accessory gland infection). Moreover, recent advances in our understanding of the causes of male infertility, particularly in the area of genetic problems (Hargreave 2000), mean that this classification is in need of review. The relative frequency of the major diagnostic categories is shown in Figure 21.6, using data taken from a WHO study of over 8500 couples from 33 centres in 25 countries (Comhaire et al 1987). It can be seen

Box 21.1 Diagnostic categories for the male partner of an infertile couple according to WHO

No demonstrable cause	Systemic causes
Idiopathic oligozoospermia	Endocrine causes
Idiopathic asthenozoospermia	Iatrogenic causes
Idiopathic teratozoospermia	Congenital abnormalities
Idiopathic azoospermia	Acquired testicular damage
Obstructive azoospermia	Varicocele
Isolated seminal plasma abnormalities	Immunological infertility
Sexual or ejaculatory dysfunction	Male accessory gland infection

that the largest single male 'diagnostic' category was men with seminal abnormalities of unknown cause. Beyond this, varicocele was a relatively common pathology, as was male accessory gland infection; however, systemic, iatrogenic and endocrine causes were very infrequent.

Genetic causes

Perhaps the most striking advances in our understanding of the aetiology of male infertility in the past decade have been in the area of genetics. Many of the 'systemic' disorders commonly associated with male infertility (see below) are now understood to have a genetic basis, and as our knowledge of the aetiology of disease expands, this will be increasingly the case. Traditionally, genetic causes of male infertility have been sought at the level of chromosomal abnormalities, with chromosomal abnormalities being detected in between 2.1% and 8.9% of men attending infertility clinics (Chandley 1994). The frequency of chromosomal abnormalities increased as sperm concentration declined, with abnormal karyotypes being found in 15% of azoospermic patients, 90% of whom had Klinefelter's syndrome (47XXY), which accounted for half of the entire chromosomally abnormal group. In oligozoospermic patients, the incidence of chromosome abnormalities was 4%. However, it has been recognized for some time that structural anomalies of the Y chromosome, resulting in deletion of the distal fluorescent heterochromatin in the long arm, are associated with severe abnormalities of spermatogenesis. More recent studies have defined a family of genes on the Y chromosome involved in spermatogenesis, and it has become clear that a little over 10% of cases of non-obstructive azoospermia may have deletions affecting these genes. A proportion of cases of very severe oligozoospermia may have a similar aetiology. Microdeletions have been found in three non-overlapping regions of the Y chromosome, AZF a-b-c. Several genes have been described and these include *RBM*, *DAZ*, *DFFRY*, *DBY* and *CDY*. The abnormality most commonly reported in the literature is a microdeletion in the AZFc region and encompassing the *DAZ* gene. However, there is no exact correlation between *DAZ* deletion and the presence or absence of spermatogenesis, but this may be because of an autosomal copy of the *DAZ* gene (Hargreave 2000). DNA fragmentation has also been identified as the cause of defective sperm function (Tarozzi et al 2007). The ability of microassisted fertilization to overcome severe deficits in spermatogenesis has reinforced the importance of understanding and investigating genetic causes of male subfertility, as these will now be transmitted to the next generation of males.

Cryptorchidism

Undescended testis is a good example of a condition present at birth, and presumed to have its origins in intrauterine life, which is significantly associated with an increased risk of impaired spermatogenesis in later life and with an increased risk of testicular cancer (Irvine 1997). The testis which is not in a low scrotal position by the age of 2 years is histologically abnormal; spontaneous descent rarely occurs after 1 year and there is little evidence that surgical orchidopexy for an undescended testis after 2 years of age improves fertility. For

these reasons, treatment should ideally be undertaken between 1 and 2 years of age. Evidence suggests that fertility may also be impaired in boys with retractile testis who experience spontaneous descent during puberty. Apart from the association with infertility, cryptorchidism is a well-established risk factor for testicular cancer, the risk of which in a patient with a history of undescended testis, whether successfully treated or not, is four to 10 times higher than in the general population.

Orchitis

Symptomatic orchitis occurs as a complication in 27–30% of males over the age of 10–11 years who suffer from mumps. In 17% of cases, orchitis is bilateral and seminiferous tubular atrophy is a common sequela of mumps orchitis, although recovery of spermatogenesis even after persistent azoospermia for 1 year has been reported (Sandler 1954). The prevalence of infertility after mumps orchitis is unknown, but fertility should only be impaired significantly if the orchitis is bilateral and occurs after puberty.

Varicocele

The subject of varicocele has generated controversy amongst the andrological community since the Edinburgh urologist Selby Tulloch first reported the apparently beneficial effects of treatment (Tulloch 1952). The available evidence certainly suggests that varicocele is a common pathology and that it is more common in men with lower sperm counts. The diagnosis of visible (grade 3) and palpable (grade 2) varicoceles is not difficult when the patient is examined in a standing position. The detection of subclinical (grade 1) varicoceles, where spermatic vein reflux can only be detected during the Valsalva manoeuvre, requires more experience and has been aided by the use of Doppler or scrotal thermography. Prevalence figures from 5% to 25% have been reported in surveys of apparently healthy men (Hargreave 1994). In contrast, amongst men attending infertility clinics, varicocele affects some 11% of men with normal semen and 25% of men with abnormal semen (World Health Organization 1992). The difficulty has been in establishing with certainty whether or not varicocele affects spermatogenesis and, most importantly, whether or not treatment of varicocele improves fertility, and if so, in which groups of men. It seems clear that varicocele is associated with abnormal semen quality, and while the mechanism of this relationship remains to be established with certainty, abnormal testicular temperature regulation is known to be associated with varicocele and impairment in semen quality.

Whatever the pathophysiology, there is a body of evidence suggesting that varicocele causes progressive testicular damage, further complicating an assessment of its role in the aetiology of male infertility. Substantial controversy exists, however, over the question of whether or not the correction of varicocele improves fertility (Evers et al 2008). Most of the appropriately designed controlled studies suggest that treatment is clearly associated with an improvement in semen quality; however, when the achievement of pregnancy is used as the endpoint, some studies find treatment to be effective while some suggest that it is of no benefit.

Occupational and environmental factors

The actively dividing male germ cells are one of the most sensitive cell types in the body with regard to the toxic effects of radiation, cytotoxic drugs and an increasing number of chemicals. Indeed, male gonadal function may be one of the most sensitive indices of overexposure to potential toxins (in the workplace, environment, foods, cosmetics and medicines) (Sharpe 2000, Bonde and Storgaard 2002). Data on occupational hazards to male reproduction remain controversial. Exposure to heavy metals, such as cadmium, lead, arsenic and zinc, has been reported to impair spermatogenesis, although the data are conflicting. Certain pesticides and herbicides have more clearly been shown to be toxic to spermatogenesis, as have some organic chemicals. The best documented modern example is the pesticide dibromochloropropane, which was responsible for azoospermic infertility in half of the male workers in a factory. There would seem to be clear evidence that occupational or environmental exposure to heat will have adverse consequences for spermatogenesis and will prolong time to pregnancy (Thonneau et al 1996). Recreational drugs such as cigarettes, alcohol and cannabis have all been linked with lower semen quality, and there is conflicting evidence on whether or not dress habit has a significant effect.

Recent data have demonstrated that male reproductive health is deteriorating, with evidence of a secular decline in semen quality (Carlsen et al 1992, Auger et al 1995, Irvine 1996), an increase in the incidence of congenital malformation of the male reproductive tract and an increase in the incidence of testicular cancer; however, there is, as yet, no evidence that these changes are having an influence on the prevalence of male infertility.

Iatrogenic infertility

Many general medical disorders are associated with male infertility, either directly (e.g. Kartagener's syndrome), indirectly as a consequence of systemic disturbance (e.g. diabetes) or as a consequence of medical or surgical intervention on account of the primary disease. A number of pharmaceuticals can impair sperm production, the most common example in clinical practice today being sulphasalazine for the treatment of inflammatory bowel diseases. A number of other drugs are also associated with detrimental effects on spermatogenesis, including nitrofurantoin, anabolic steroids, sex steroids and anticonvulsants. Cytotoxic treatment regimes for Hodgkin's disease, lymphoma, leukaemia and other malignancies damage the differentiating spermatogonia, so that most patients become azoospermic after 8 weeks. The degree of stem cell killing governs whether there is recovery of spermatogenesis or not after treatment. This is dependent on the cumulative dose of the drug combination used. Long-term follow-up has shown that following six or more courses of MOPP (mustine, vincristine, procarbazine and prednisolone), over 85% of patients remained azoospermic and recovery is unlikely after 4 years. Similarly, radiation exposure of over 6 Gy destroys germ cells with no chance of recovery. While 1–4 Gy produces complete cessation of spermatogenesis with only some stem spermatogonia surviving, there may be recovery after 12–36 months. Spermatogenesis may

continue to improve for several years, but even then it may not be complete.

Genital tract obstruction

The combination of azoospermia, normal testicular volume and normal FSH are the hallmarks of genital tract obstruction. The incidence and relative importance of individual causes of obstruction differ according to geographic locality. Postcongenital and postvasectomy obstructions are the most common, but in some parts of the world, infectious causes, particularly gonorrhoea and tuberculosis, are of greater importance.

The most common congenital abnormality is agenesis or malformations of the Wolffian-duct-derived structures: the corpus/cauda epididymis, vas deferens and seminal vesicles. Diagnosis is usually quite easy; the scrotal vasa are not palpable and the ejaculate consists of low volumes (>1 ml) of acidic non-coagulating prostatic fluid devoid of fructose and sperm. Congenital bilateral absence of the vas deferens is associated with *CFTR* mutations and is found in approximately 2% of men with obstructive azoospermia (Hargreave 2000). In recent years, increasing numbers of mutations of the *CFTR* gene have been characterized and more than 400 have been described. In general, the more mutations tested for, the higher the percentage of men found to have mutations. As such, in more recent publications, detection rates have been almost 70–80%.

Male accessory gland infection

The second most common diagnostic grouping in the WHO survey is also an area of considerable aetiological controversy. Infection in the lower genital tract can be a treatable cause of male infertility, and the incidence varies in different communities. Gram-negative enterococci, chlamydia and gonococcus are established pathogenic organisms which usually produce unequivocal clinical evidence of infection (adnexitis), such as painful ejaculation, pelvic or sacral pain, urethral discharge, haematospermia, dysuria, irregular tender epididymides and tender boggy prostate. This can be confirmed by semen culture and urethral swabs. Inflammation of the accessory glands and excurrent ducts may give rise to disturbed function, formation of sperm antibody and permanent structural damage with obstruction in the outflow tract.

Thus, whilst there is little doubt that overt sexually transmitted disease may damage male fertility and should be appropriately managed, there is much more doubt about the relevance of subclinical infection. The entity of asymptomatic prostatitis is poorly defined and there is little evidence to support a genuine role for occult infections in male infertility. There is thus no place for microbiological screening investigations unless there is clinical suspicion of adnexitis. Furthermore, the isolation of non-pathogenic organisms such as staphylococcus, streptococcus, diptheroids, *Ureaplasma urealyticum* and *Mycoplasma hominis*, which are commensals in the normal urethra, does not warrant the indiscriminate use of antibiotics in the hope of correcting any abnormalities in the semen parameters.

One possible consequence of seminal leucocytosis is the excessive generation of reactive oxygen species (ROS). There

is good evidence linking the excessive generation of ROS with male infertility as an aetiological entity in its own right; prospective studies have shown that couples with elevated levels of ROS generation are less likely to conceive either spontaneously or in the context of in-vitro fertilization (IVF).

Immunological causes

Suspected immunological infertility was found in some 3% of couples in a WHO survey on the basis of the finding of 10% or more of motile spermatozoa coated with antibody using assays such as the Immunobead test or the mixed antiglobulin reaction. Whilst antisperm antibodies are found in perhaps one in six of the male partners of infertile couples, a prevalence which is higher than that for fertile controls, their effect on fertility is hard to determine. Some studies suggest that 'antibody-positive' couples conceive at a lower rate than those without immunological problems. Unfortunately, antibodies to sperm surface antigens are also found in fertile control populations, and current techniques do not permit the meaningful separation of cases with autoimmunity to biologically relevant epitopes (Paradisi et al 1995). Given the consensus view that assisted conception is the treatment of choice, this may not now be a clinically relevant issue.

Gonadotrophin deficiency

The clinical features of gonadotrophin deficiency depend on the cause and time of onset, in particular whether the man is pre- or postpubertal. The spectrum includes patients with complete congenital deficiency in GnRH, which results in total failure of testicular and secondary sexual development. Other patients have less severe or partial GnRH deficiency, so have larger (4–10 ml) but still underdeveloped testes with more evidence of germ cell activity; this may be described as the so-called 'fertile eunuch syndrome'. In three-quarters of these patients, anosmia or hyposmia and a variety of midline defects can be detected; this is the association known as 'Kallmann's syndrome'.

In contrast to these congenital varieties of isolated hypogonadotrophic hypogonadism, postnatally or postpubertally acquired gonadotrophin deficiency may arise from tumours, chronic inflammatory lesions, iron overload or injuries of the hypothalamus and pituitary, so that deficits in other pituitary hormones usually coexist. These patients have developed seminiferous tubules which have regressed through lack of trophic hormone support. Their testicular volumes are larger (10–15 ml) than in the former two groups.

Gonadotrophin treatment of these syndromes is discussed below. Androgen treatment is required by hypogonadal men for long-term replacement, and is generally given by injection of testosterone esters every 3–4 weeks, aiming to maintain plasma testosterone concentrations in the physiological range. This is made more difficult by the high peaks and low troughs following administration of these preparations; monitoring of dosage should take place immediately before subsequent injection (i.e. at the trough). Other preparations include the orally active testosterone undecanoate, transdermal patches, gels and subcutaneous testosterone pellets.

Undecanoate is largely confined to paediatric practice for pubertal induction as circulating concentrations tend to be low. Testosterone patches frequently cause skin irritation, although this is not a problem with the gels as these do not contain the enhancers necessary to promote absorption across the skin. New injectable esters are becoming available with a longer duration of action, with up to 3 months between administration (Srinivas-Shankar and Wu 2006). Testosterone will restore sexual interest and activity, and penile erections during and on waking from sleep. Other symptoms of testosterone deficiency include tiredness, irritability and loss of body hair. Testosterone will not induce or improve fertility, and there is no place for androgen treatment of men wishing to conceive.

Coital disorders

Inadequate coital technique (including the use of vaginal lubricants with spermicidal properties) and frequency and faulty timing of intercourse may contribute to continuing infertility, but are rarely the only aetiological factors in the infertile couple. Erectile and ejaculatory failure may be caused by psychosexual dysfunction, depression, spinal cord injuries, retroperitoneal and bladder neck surgery, diabetes mellitus, multiple sclerosis, vascular insufficiency, adrenergic blocking antihypertensive agents, psychotropic drugs, alcohol abuse and chronic renal failure. Primary endocrine pathologies such as androgen deficiency, hyperprolactinaemia and hypothyroidism seldom present with infertility without diminished libido and clinical features specific to the hormonal disturbances. Retrograde ejaculation must be differentiated from aspermia or anejaculation by examination of postejaculatory urine for the presence of spermatozoa.

Idiopathic impairment of semen quality

Regrettably, this descriptive label continues to be required for a very substantial proportion of men attending infertility clinics. Failure of seminiferous tubular function to the extent of producing azoospermia or severe oligozoospermia (>5 million) is usually associated with small (under 15 ml) and soft testes and elevated FSH. Histologically, the tubules may show completely absent or reduced numbers of germ cells, narrow tubular diameter, and thickening and hyalinization of peritubular tissue. These changes are non-specific and are not always uniformly distributed throughout the testes. There is no evidence to support the contention that testosterone deficiency is the primary cause of defective spermatogenesis, nor that abnormalities in GnRH pulse frequency may be the underlying cause of idiopathic hypospermatogenesis. These patients usually remain infertile and there is no curative treatment available. Less severe degrees of oligozoospermia are commonly associated with abnormal morphology and reduced motility.

'Asthenozoospermia' is the descriptive term applied to impaired sperm motility. Absent or extremely low sperm motility of only 1–2% may result from absence of dynein arms, radial spokes or nexin bridges, and dysplasia of fibrous sheath. This is associated with similar defects in respiratory cilia and therefore, frequently, a history of chronic respiratory infection, bronchiectasis and sinusitis: the 'immotile

cilia syndrome'. In addition, some of these patients have situs inversus (Kartagener's syndrome). Based on this classic but extremely rare example, it is now becoming clear that more common but less severe degrees of asthenozoospermia may also be associated with more subtle structural malformations in the axonemal complex, recognizable only with ultrastructural examination and functionally evident as suboptimal sperm movements.

'Teratozoospermia' is the term used to describe altered morphology. Surface morphology directly reflects the maturity and functional integrity of the spermatozoa so that morphological analysis of ejaculated sperm is an important means of assessing spermatogenesis in the testis. Indeed, some workers believe that sperm morphology is the best predictor of spontaneous fertility or the outcome of IVF (Kruger et al 1995). It has been reported that morphology in the individual spermatozoon is related to movement characteristics (swimming velocity, sperm head trajectories, flagellar beat frequency) and its ability to exhibit hyperactivation. Similarly, the ability to undergo the acrosome reaction has also been shown to be significantly higher in sperm with morphologically normal, compared with abnormal, sperm heads. Ultrastructural studies have also revealed a variety of structural malformations of the acrosome complex, the most extreme example being the round-headed sperm where the acrosome is completely missing, but lesser degrees of acrosomal defects are increasingly being identified. These attempts to relate specific functional defects to recognizable structural malformations in individual spermatozoa provide evidence that morphologically abnormal sperm are also functionally impaired.

Clinical Management

The essence of clinical management is to assess the prognosis (chances of conception per year or per cycle of assisted conception) and to advise the couple as to those treatment options that should improve the prognosis. This advice is based upon a sound knowledge of the causes of infertility and the treatment options available. In doing this, it is important to recognize that a number of general epidemiological factors will have a bearing on a couple's fertility. Examples of this include age, although the impact of male age is less certain. Similarly, a longer duration of infertility, even when allowing for age, results in a reduction in fertility. On the other hand, the occurrence of any previous pregnancy will enhance the outcome of treatment after IVF.

Recent advances in assisted conception technology have revolutionized the management of couples with male factor infertility, and have advanced our understanding of the aetiology of male infertility by drawing attention to the major contribution of genetic factors. Paradoxically, they have also encouraged a minimalist clinical approach to the diagnosis of men with fertility problems, given the limited range of effective therapeutic options. The dangers of this approach have been highlighted in the light of existing concerns over the safety of microassisted fertilization (Cummins and Jequier 1994).

Many clinicians endeavour to manage male infertility at a distance, a request for semen analysis preceding, even substituting for, taking a history from and performing a physical

examination of the male partner. Those who take this attitude do their patients a disservice; they foster the idea that the male contribution to infertility is limited and while a semen analysis will only occasionally provide the clinician with a diagnosis, a careful history and examination may identify the cause of a couple's infertility. A number of significant features of the clinical history, together with their associated rates of azoospermia or abnormal semen quality, are shown in Table 21.1.

History

Infertility is, of course, the problem of a couple and must be managed as such, with the history being taken from both partners together. The duration of the present union and the duration of infertility complained of should be established at the outset, together with the history of any pregnancies for which the individual may have been responsible. In the patient's past medical history, areas which should receive special attention are a history of mumps virus infection, the age at which this occurred and whether or not there was an associated orchitis. As can be seen from Table 21.1, 84% of men with a history of bilateral mumps orchitis have abnormal semen and 22% are azoospermic. Diabetes mellitus and certain neurological diseases are known to be associated with ejaculatory disturbances, and

Table 21.1 Features in the clinical history with an influence on male fertility and their associated rates of azoospermia and abnormal semen quality

Feature	% of cases with azoospermia	% of cases with abnormal semen
Diabetes mellitus	16.7	60.0
Bronchiectasis	32.0	82.4
Higher fever	5.2	64.4
Long-term medication	12.3	52.9
Urinary tract infection	8.9	60.1
Sexually transmitted disease	7.6	50.4
Epididymitis	17.3	70.2
Testicular injury	12.6	56.9
Testicular torsion	18.2	88.9
Unilateral maldescent	20.8	65.7
Testicular maldescent (bilateral)	40.8	75.9
Mumps orchitis (bilateral)	22.0	84.4
Excessive alcohol consumption	9.6	51.8

From Cornhaire FH, de Kretser D and Farley TMM Towards more objectivity in diagnosis and management of male infertility. Results of a WHO Multicentre Study. International Journal of Andrology 1987; 10(S7): 1–53.

a history of these or of any other systemic illness should be sought, as should a history of recent pyrexial illness as this may compromise spermatogenesis for many weeks. A history of respiratory disease should be sought carefully, including recurrent respiratory tract infections, sinusitis, bronchiectasis or cystic fibrosis, as these conditions can be associated with ciliary dysfunction and therefore with impaired sperm motility, as in Kartagener's syndrome, or with obstructive azoospermia, as in Young's syndrome. As many as 82% of men with a history of bronchiectasis have abnormal semen and 32% are azoospermic. Parasitic diseases, such as schistosomiasis and filariasis, are rare but must be borne in mind as potential causes of excurrent duct obstruction and prostatovesiculitis.

Any symptomatology related to the urinary tract, such as dysuria, urethral discharge, frequency or haematuria, is of self-evident importance. Likewise, aspects of the specific reproductive history which are of importance include any history of testicular maldescent, injury, torsion or epididymo-orchitis, and any history of surgery which may have compromised the genital tract, such as herniorrhaphy, orchidopexy, drainage of hydrocoele, ligation of a varico-coele or bladder neck surgery. Other specific conditions may impair reproductive performance, and a group of patients now requiring infertility investigations are those who have survived treatment for testicular or lymphatic malignancy and who may suffer the consequences of chemotherapy, radiotherapy or retroperitoneal lymph node dissection. A history of drug ingestion, including sulphasalazine, cimetidine or nitrofurantoin, or of exposure to other toxins, including alcohol and tobacco, known to impair spermatogenesis is important, as is the occupational history in terms of exposure to toxic chemicals and hyperthermia. The sexual history should endeavour to cover the adequacy of erectile function and if there is doubt, the presence of early morning and masturbatory erections should be enquired into in order to differentiate organic from psychogenic impotence. The occurrence of intravaginal ejaculation should be established and again, if there is doubt, the occurrence of nocturnal or masturbatory ejaculation sought, in addition to which the characteristics of ejaculation such as associated pain, prematurity or delay should be established. A number of couples attending infertility clinics will be infertile as a consequence of sexual dysfunction, and a number of couples with sexual dysfunction will present to infertility clinics seeking primary help. Of course, any history of sexually transmitted disease and its outcome is of note, as is a history of drug abuse or of other factors exposing the patient to high risk of infection with human immunodeficiency virus, due to the problems which this poses for the couple in terms of the risks of transmission and pregnancy, and in terms of the problems presented to laboratory staff handling blood and semen samples.

Examination

The examination of the male partner should include a general medical examination covering height and weight, blood pressure and all of the major systems, including the respiratory system. The secondary sexual development of the patient must be assessed and signs of hypogonadism sought, including examination of the visual fields, to assess pituitary

Figure 21.7 Prader orchidometer for the assessment of testicular volume. From L Hagenäs, *Normal och avvikande pubertet hos pojkar*, Journal of the Norwegian Medical Association, 2008; 128:1284–8.

enlargement, and examination of the sense of smell to exclude Kallmann's syndrome if indicated. Gynaecomastia should be specifically examined for in this context. On examination of the abdomen, it is important to note the presence of scars or lymphadenopathy in the groins.

Turning to the urogenital examination, the penis is examined for evidence of phimosis, hypospadias, epispadias or the characteristic plaques of Peyronie's disease. The scrotum should be examined and the site of the testes determined, following which the testicular volume in millilitres should be determined with the aid of a Prader orchidometer (Figure 21.7) and their consistency evaluated. It is known that a clear relationship exists between testicular volume and sperm production. Any tenderness of the gonads should be noted and the epididymides carefully palpated from caput to cauda to exclude thickening, tenderness, cystic lesions, atrophy or absence of the epididymides. The vasa deferentia should next be palpated to establish that they are not congenitally absent and any thickening or induration should be noted. Scrotal swellings, such as hydrocoele or hernia, should be noted and the presence and grade of varicocele should be established by asking the patient to perform Valsalva's manoeuvre. The inguinal regions should be inspected for hernia, scarring or the presence of lymphadenopathy. A rectal examination should be performed to assess the state of the prostate and seminal vesicles, although this seldom provides useful information and may be omitted unless ejaculatory duct obstruction or prostatovesiculitis is suspected.

Semen analysis

The conventional criteria of semen quality have changed little since van Leeuwenhoek first described spermatozoa in the human ejaculate in 1685. A standard semen analysis, performed according to clearly established guidelines

Box 21.2 Normal values of semen analysis

Volume	2.0 ml or more
pH	7.2–7.8
Sperm concentration	$20 \times 10^6/\text{ml}$ or more
Motility	50% or more with progressive motility (grade 1 + 2) within 60 min of ejaculation
Morphology	Normal morphology below 15% is associated with reduced fertilization rates in the context of IVF
Viability	75% or more live
White blood cells	Fewer than $1 \times 10^6/\text{ml}$
Mixed antiglobulin reaction test	Fewer than 10% spermatozoa with adherent particles

promulgated by WHO (World Health Organization 1999) (Box 21.2), provides descriptive information concerning sperm number, motility and morphology, together with aspects of the physical characteristics of the ejaculate.

Sample collection and delivery

The sample should be collected after a minimum of 48 h and not longer than 7 days of sexual abstinence. Two semen samples should be collected for initial evaluation, not less than 7 days or more than 3 months apart. This is in order to take account of the effects of interejaculate variability and length of abstinence that are known to occur. The sample should be collected by masturbation into a clean wide-mouthed glass or plastic container and delivered to the laboratory within 1 h of collection, if it is not possible for the patient to produce the sample at the laboratory. The sample should be evaluated by inspection and should normally be grey-opalescent and homogeneous, liquefying within 60 min. Abnormalities of appearance or failure of liquefaction are noted, following which the semen volume is measured. Abnormally low volumes are commonly due to incomplete sample collection, but may be due to ejaculatory dysfunction. A normal sample has a volume of 2.0 ml or more. The consistency or 'viscosity' of the liquefied sample should be evaluated, and the pH of the sample should be in the range of 7.2–7.8.

Microscopic evaluation

Motility

One hundred spermatozoa are examined at $\times 400$ – 600 , preferably using phase contrast optics, and their motility is assessed and subjectively graded as rapid and linearly progressive motility (grade 4), slower and sluggish linear or non-linear movement (grade 3), non-progressive motility (grade 2) or immotile (grade 1). The percentage of spermatozoa in each category is scored, WHO criteria requiring 50% or more cells with grade 3 or 4 motility. Epithelial cells, spermatogenic cells and white blood cells may be seen, their concentration in a normal sample being less than $1 \times 10^6/\text{ml}$. If more are present, a specific stain should be

performed for peroxidase-positive white blood cells. The adherence of spermatozoa to each other (agglutination) is noted and reported on an arbitrary scale. If the percentage of immotile spermatozoa exceeds 60%, the proportion of live spermatozoa may be determined.

Sperm concentration

This should be determined accurately by diluting a portion of the semen sample with a diluent to immobilize the spermatozoa and then loading this diluted preparation into a standard haemocytometer, the number of spermatozoa being counted by standard techniques and the result expressed as the concentration of spermatozoa ($\times 10^6/\text{ml}$). This should be at least $20 \times 10^6/\text{ml}$.

Morphology

A smear slide of fresh semen is prepared, air dried, stained by the Giemsa, modified Papanicolaou or Bryan-Leishman methods and examined by light microscopy for the various morphological abnormalities which are described. The result is expressed as the percentage of spermatozoa which are morphologically normal.

In addition to the above, a number of supplementary procedures may be undertaken in the evaluation of human semen, including semen culture, and biochemical evaluation for quantitation of acid phosphatases, citric acid and zinc (as markers of prostatic function), fructose and prostaglandins (as markers of seminal vesicular function) and free L-carnitine (as a marker of epididymal function). WHO has issued a statement of the commonly accepted normal values for the parameters discussed above (Box 21.2), although making the point that it is preferable for each laboratory to establish its own normal ranges for each variable, by evaluating semen from individuals of proven fertility amongst its own local population. It is anticipated that a revised analysis of sperm norms will be published soon by WHO.

Antisperm antibodies

The mixed agglutination reaction uses sheep red blood cells coated with rabbit antibodies to specific classes of human immunoglobulins, which will attach to motile sperm carrying immunoglobulins of the same class on their surface membrane (Bronson et al 1984). This permits the detection of immunoglobulin gamma A, G or M on the surface of the sperm head or tail. The direct test uses washed sperm from the patient, and the presence of surface-bound antibody, indicated by particulate binding in over 10% of spermatozoa, is considered to be a positive result. It depends on the availability of sufficient numbers of motile sperm in the patient's fresh semen sample and is currently the standard screening test in most laboratories. The indirect test uses decanted patient serum or seminal plasma which is incubated with motile donor sperm, and is known as the 'tray agglutination test'. Antisperm antibodies will bind to donor sperm and their presence is detected by attachment of particles to the sperm surface. The indirect test is therefore more convenient for screening larger numbers of patients. A positive screening test, however, must be substantiated by investigations to assess the biological significance of sperm antibody.

Additional diagnostic tests on semen

Although of central importance in the evaluation of the male partner of an infertile couple, the conventional criteria of semen quality are of a purely descriptive nature and there is widespread agreement that this information is of limited value in providing an assessment of the ability of a given individual to achieve a pregnancy. In an attempt to overcome this problem, numerous additional tests of sperm function have evolved, including the study of human sperm movement characteristics, initially by time-exposure photomicrography and more recently by computer-assisted image analysis, the study of the penetration of human spermatozoa into cervical mucus and the zona-free hamster oocyte penetration test. This latter test examines a number of key aspects of human sperm function, including the ability of spermatozoa to capacitate, acrosome react and fuse with the vitelline membrane of the oocyte. More recently, biochemical tests, such as measurement of ROS production, have been developed. Although many of the advanced sperm function tests that have been described provide valuable diagnostic information in the hands of competent laboratories, they are typically difficult to perform and have poor predictive values when more widely applied. They are useful research tools and capable of identifying some of the specific causes of infertility. In clinical practice, IVF remains the best test of sperm function, and failed fertilization is probably best treated by intracytoplasmic sperm injection (ICSI).

Hormone measurements

The measurement of plasma FSH is useful in distinguishing primary from secondary testicular failure and in identifying patients with obstructive azoospermia. In the presence of azoospermia or oligozoospermia, an elevated FSH, particularly with reduced testicular volume, is presumptive evidence of severe and usually irreversible seminiferous tubular damage. Low or undetectable FSH (usually associated with low LH and testosterone, with clinical evidence of androgen deficiency) is suggestive of hypogonadotrophism. Conversely, azoospermia with normal FSH and normal testicular volume usually indicates the presence of bilateral genital tract obstruction. Occasional exceptions to these general rules occur from time to time, as azoospermic men with the Sertoli cell only syndrome may have normal FSH levels, while some men with high FSH may have normal spermatogenesis.

Testosterone and LH measurements are indicated in the assessment of the infertile male when there is clinical suspicion of androgen deficiency, sex steroid abuse or steroid-secreting lesions such as functioning adrenal/testicular tumours. In men presenting with infertility, testosterone is usually within the normal range although some degree of Leydig cell dysfunction, as evidenced by statistically lower testosterone and higher LH compared with normal, is not uncommon. This may identify those who may be considered for androgen replacement, although this has no bearing on fertility. High LH and testosterone should raise the possibility of abnormalities in androgen receptors, while low LH and testosterone suggest hypogonadotrophism.

Hyperprolactinaemia is not a frequent cause of male infertility, but prolactin measurement should be undertaken if

there is clinical evidence of sexual dysfunction (particularly loss of interest in sex) or pituitary disease leading to secondary testicular failure. Oestradiol measurement is rarely indicated except in the presence of gynaecomastia, which is also a feature of Klinefelter's syndrome.

Dynamic tests of pituitary–testicular function such as GnRH, thyrotrophin-releasing hormone and human chorionic gonadotrophin stimulation generally do not add to the basal measurements described above. Bearing in mind the episodic nature of LH secretion, the diurnal variation in testosterone and the stress-related secretion of prolactin, it is usually sufficient to repeat their measurements in the morning, under resting conditions if necessary.

Chromosome analysis

Chromosome karyotyping should be carried out in patients with azoospermia or severe oligospermia with reduced testicular volumes and elevated FSH. Cytogenetic abnormalities, by far the most common being Klinefelter's syndrome, may be detected in approximately 10% of this group and are of importance if treatment by ICSI is being contemplated. Although still only research, screening for microdeletions on the Y chromosome is likely to enter routine clinical practice in the near future (Krausz and Degl'Innocenti 2006).

Testicular biopsy

With the use of plasma FSH to differentiate between primary testicular failure and obstructive lesions, the need for testicular biopsy in the investigation of male infertility has largely been superseded, although it clearly has a place in the surgical retrieval of sperm for ICSI. When genital tract obstruction is suspected, testicular biopsy is useful in confirming normal spermatogenesis and excluding spermatogenic arrest, but should only be undertaken under circumstances where sperm may be stored for subsequent use in assisted conception. When the clinical differentiation between spermatogenic failure and obstruction is uncertain (e.g. asymmetrical findings on examination between right and left testes or adnexae), scrotal exploration with testicular biopsy may be helpful, again with facilities for sperm storage to hand. Vasography during scrotal exploration is required to confirm the diagnosis of obstructed ejaculatory ducts. It is important to remember that even in primary testicular failure with small testes, elevated levels of FSH and a testicular biopsy showing Sertoli cell only syndrome, some areas of spermatogenesis may be present in the testis. There are many techniques for describing the appearances of a testicular biopsy, but the combination of words and a qualitative assessment, using Johnsen scoring (Johnsen 1970), is useful. In the Johnsen score, the histological features of spermatogenesis are scored from 1 to 10 (2, Sertoli cell only; 3, spermatogonia; 4, 5, spermatocytes; 6, 7, spermatids; 8, 9, 10, spermatozoa).

Treatment

The management of male infertility often remains a difficult and somewhat unsatisfactory experience for patients as well as doctors. Many patients present no recognizable or reversible aetiological factors for treatment, and the doctor

frequently fails to appreciate that normal semen values do not relate to fertility. In recent years, there have been a number of advances which have made a significant impact on our therapeutic capabilities. It is important to improve semen quality and to treat those factors that impair fertility.

General measures

Although much has been written about the nature of general advice which should be given, objective evidence for its efficacy in improving fertility is sadly lacking (Bonde and Storgaard 2002). Commonly raised issues include avoidance of stress, a healthy diet and exercise. Recreational drugs such as cigarettes, excessive alcohol consumption and cannabis should certainly be withdrawn or reduced if possible. Occupational or social situations that may chronically elevate testicular temperature should be avoided. Medications that interfere with fertility, such as nitrofurantoin, anabolic steroids, sex steroids and anticonvulsants, should be avoided if possible. In patients with inflammatory bowel disease treated by sulphasalazine, changing treatment to 5-aminosalicylic acid removes the toxic agent, sulphapyridine, and leads to a rapid recovery of fertility without deterioration in disease activity. Although testicular function may improve in patients with chronic renal failure after successful transplantation, fertility impairment may be perpetuated by the continued use of immunosuppressive agents.

Medical treatment

Perhaps the most important point to stress is that empirical treatments for idiopathic oligozoospermia, such as antioestrogens, androgens, bromocriptine and kinin-enhancing drugs, have not been shown to be effective in the treatment of men with abnormalities of semen quality and they should not be used. Although free radicals undoubtedly have a role to play in male infertility (Aitken 1989), few centres measure them routinely and there is, as yet, no evidence that the antioxidant treatments which are used on an empirical basis are effective. Endocrine treatment is only effective in the presence of specific endocrine disturbances, which are rare.

Management of gonadotrophin deficiency

Patients with gonadotrophin deficiency due to acquired conditions and those with GnRH deficiency usually respond to human chorionic gonadotrophin (1000–3000 IU once or twice weekly) alone for 6–12 months (Burger 1982). During this time, the rise in testosterone will virilize the patient and the testes will usually increase in size. If there are no sperm in the ejaculate at the end of 6–12 months, FSH should be added, usually in the form of human menopausal gonadotrophin which contains both FSH and LH. This graded approach may take up to 2 years before one can ascertain if spermatogenesis is established or not. Longer-acting gonadotrophin preparations might be of clinical value in this context.

The treatment outcome of gonadotrophin induction of spermatogenesis is relatively successful, with up to 90% showing some degree of spermatogenesis. Up to 70% can be expected to achieve pregnancies (Büchter et al 1998, Liu et al 2002). Previous treatment with testosterone does not

compromise the response to subsequent exogenous gonadotrophin, but there is a clear relationship between pretreatment testicular volume and duration of treatment required. Thus, spermatogenesis will generally be restored more quickly and with less frequent need for FSH in men with acquired gonadotrophin deficiency in adulthood (e.g. as a result of treatment for a pituitary tumour) than in those who have not gone through puberty spontaneously.

Management of genital tract infection

Infection of the male genital tract should be treated if present, but there is no evidence that this will improve fertility. Symptomatic urethritis responds to treatment with the appropriate antibiotics. Chronic infection of the male genital tract is more difficult to diagnose and the presence of pus cells in the semen only indicates an infection in some patients. An alkaline pH (>8.0) may occur in prostatitis due to decreased secretion of acid phosphatase by the prostate. Repeated growth on culture of the same organisms is probably of significance, as is the finding of organisms during a modified Stamey test (Meares and Stamey 1972), where the semen culture replaces the culture of expressed prostatic secretions. If treatment is felt to be warranted, the antibiotics chosen to treat prostatoseminal vesiculitis (such as doxycycline, erythromycins, cephalosporins or ofloxacin) should be secreted by the male accessory glands, and treatment should be continued for 4–12 weeks depending on the chronicity of the infection. In longer courses of treatment, it is customary to rotate the antibiotics, but overall the current tendency is towards a shorter duration (6 weeks) of treatment consisting of two antibiotics, each of which is taken for 3 weeks.

Management of antisperm antibodies

The presence of antisperm antibodies may be a cause of male factor infertility. The use of systemic corticosteroids for treatment of antisperm antibodies remains controversial and can only be recommended in the context of further research as the evidence of benefit is conflicting and there are potentially serious side-effects. Commonly, treatment by assisted conception is recommended.

Erectile failure

The inability of the man to obtain vaginal penetration may be overcome by various pharmacological approaches, and this is particularly useful in men with neurological problems or with performance anxiety. If intracavernous agents are used, the physician should be familiar with the technique and avoid the tragedy of a priapism. Papaverine was the drug of choice for many years but this has been superseded by alprostadil, a prostaglandin E_1 preparation, and more recently by oral sildenafil and other phosphodiesterase type 5 inhibitors (Hackett G, Kell P, Ralph D et al, British Society for Sexual Medicine 2008). In those men with organic impotence, the implantation of a penile prosthesis may provide a solution to the problem.

Ejaculatory failure

Absent emission or retrograde ejaculation due to sympathetic denervation may respond to sympathomimetic drugs. The first choice is desipramine (50 mg on alternate days) for its noradrenaline reuptake blocking action. Ephedrine 30 mg

twice daily, brompheniramine maleate 8 mg twice daily or imipramine 25 mg three times daily may also be tried. It is always worth trying desipramine in those men with a diabetic autonomic neuropathy. Urine inhibits sperm motility and, for this reason, spermatozoa should be separated from the urine as soon as possible and used for artificial insemination or assisted conception. Surgical reconstruction of the bladder neck is rarely required.

Surgical treatments

Surgery on the male genital tract should only be carried out in centres where there are appropriate facilities and trained staff. Vasectomy reversal is an effective treatment for men who want to reverse their sterilization, and surgical correction of epididymal blockage can be considered in cases of obstructive azoospermia. Testicular biopsy should only be performed in the context of a tertiary service where there are facilities for sperm recovery and cryostorage.

Relief of obstruction

Obstructive lesions of the seminal tract should be suspected in azoospermia or severe oligozoospermia with normally sized testes and with normal plasma FSH levels. Where surgery is undertaken, it is convenient to explore and biopsy the testes, perform vasography and correct any obstruction that is identified under the same general anaesthetic. A fuller account of the indications, techniques and outcomes of surgical treatments of male infertility may be found elsewhere (Pryor et al 1997).

Epididymal obstruction

The results of reconstructive surgery on the epididymis are varied and depend upon the cause and duration of obstruction and the expertise of the surgeon. Congenital blockages have poor outcome, as do blockages resulting from tuberculous or chlamydial infections. The overall patency rate would appear to be approximately 10–15% of operations, as in many patients there is a great deal of scarring and the epididymis is filled with inspissated material. The best results are achieved when there is localized postgonococcal obstruction in the cauda epididymis. In these instances, sperm may appear in 50% of ejaculates after surgery. A microsurgical technique would appear to give a 10% improvement in patency rates. Spermatozoa acquire motility as they pass through the epididymis, and higher pregnancy rates occur when the blockage is in the distal part of the epididymis (Schoysman and Bedford 1986).

Vasal obstruction

Vasal obstruction is less common in infertility practice and is treated by vasovasostomy. Many techniques are described but an end-to-end one-layer anastomosis with 6-0 sutures is simple and effective. Vasal obstruction most commonly occurs following vasectomy, and after vasovasostomy, patency is to be expected in 80–90% of men with a conception rate of 40–50% in 1 year. Magnification is desirable and the use of an operating microscope for vasovasostomy is excellent training for the more difficult tubulovasostomy that is necessary in epididymal obstruction. The prognosis is worse for those men with a long interval between the vasectomy and reversal (Silber 1989), but time does not

prohibit any attempt to operate. The age of the female partner is of importance with regard to conception rates.

Ejaculatory duct obstruction

This is an uncommon cause of obstruction and is readily diagnosed by a low volume of semen, azoospermia or extreme oligozoospermia, and an acid pH in a man with palpable vasa. Müllerian duct cysts are amenable to treatment (Pryor et al 1997), with sperm appearing in the ejaculate of 80% of men and conception in 33% of female partners. Other forms of ejaculatory duct obstruction do less well and are probably best treated by sperm retrieval.

Varicocele treatment

As discussed above, this remains an area of considerable controversy. Varicocele is a common finding amongst an infertility clinic population. In trying to interpret the available evidence and decide whether and when to treat, it is wise to remember the many other factors that have a considerable bearing on a couple's fertility. There is no evidence to suggest that treating varicocele in the presence of normal semen quality is beneficial. Available evidence does suggest that treatment in men with oligozoospermia will improve semen quality, but evidence on whether this will result in pregnancy remains unclear, probably due to the heterogeneous populations studied. It is clear that any benefit is not substantial, and in many cases, particularly where the female partner is above 35 years of age, the duration of the couple's infertility is prolonged or the deficit in semen quality is severe, assisted conception techniques have more to offer.

Assisted conception and male infertility

Early developments in IVF focused on couples with female factor infertility and particularly women suffering from bilateral tubal occlusion. Conventional IVF rapidly became established as an effective treatment option for couples with tubal disease and with unexplained infertility, but it soon became apparent that it yielded generally poor pregnancy rates for couples with male factor infertility. Although there was much discussion in the literature on the fine tuning of the IVF procedure for couples with problems in the male partner, management options for couples with poor semen quality remained very limited until the breakthrough of effective microassisted fertilization in 1992 (Palermo et al 1992).

Micromanipulation techniques

Partial zona dissection was the first micromanipulation technique studied in animal models with clinical intent, and early reports in human practice of clinical pregnancies were encouraging, suggesting that monospermic fertilization and cleavage rates could be doubled by these approaches. However, concerns existed over the risk of polyspermy, along with doubts about appropriate case selection. Subzonal insemination (SUZI) involves the injection of spermatozoa into the perivitelline space; again, initial reports of its use were encouraging, although other groups found the technique to be less successful. The developments in human microassisted fertilization culminated in ICSI, with the first human pregnancies resulting from this technique being described by the Brussels group (Palermo et al 1992). This

approach involves injection of a single spermatozoon directly into the cytoplasm of the oocyte through the intact zona pellucida, and it very soon became apparent that this technique produced superior results to partial zona dissection or SUZI, with pregnancy rates of 22% per started cycle being reported (Van Steirteghem et al 1993, Abdalla et al 1995). Indeed, such has been the success of ICSI that some commentators suggest that it might be considered the treatment of choice for all cases where in-vitro conception is indicated.

A meta-analysis has concluded that for couples with normal semen, there is no evidence of any benefit, either in fertilization rates per retrieved oocyte or in pregnancy rates, between ICSI and conventional IVF. In contrast, for couples with borderline semen, ICSI results in higher fertilization rates than IVF, and couples with very poor semen will have better fertilization outcomes with ICSI than with SUZI or additional IVF (van Rumste et al 2000).

ICSI with epididymal spermatozoa

Initially, clinical ICSI was used in the treatment of couples in whom the male partner had substantially abnormal semen quality, but it was not long before the technology was applied to the significant numbers of men who present with no sperm in their ejaculates. Amongst men with obstructive azoospermia, attention focused on spermatozoa derived from the epididymis. The first pregnancies achieved with epididymal sperm were described using conventional IVF. However, fertilization rates were low, so whilst it was established that sperm from the epididymis had a degree of functional competence, this was limited (Liu et al 1994, Silber et al 1994).

As a consequence of the successful use of epididymal spermatozoa in ICSI, techniques have been described to facilitate the surgical retrieval of spermatozoa. The major approaches include microsurgical epididymal sperm aspiration (MESA) and percutaneous epididymal sperm aspiration (PESA). MESA involves a formal scrotal exploration, is commonly performed under general anaesthetic and hence is a significant surgical intervention. PESA is a widely used technique which is less invasive, can be performed under local anaesthesia and can be undertaken repeatedly. However, PESA provides less diagnostic information and the yield of spermatozoa may be lower (Girardi 1999).

ICSI with testicular spermatozoa

In contrast to the position in men with obstructive azoospermia, amongst men with non-obstructive azoospermia, attention naturally focuses on the testis as a site for sperm recovery. With the availability of ICSI, it has become clear that non-obstructive azoospermia is a very heterogeneous condition and that testicular histology is similarly heterogeneous, with foci of apparently normal spermatogenesis adjacent to seminiferous tubules devoid of germ cells. Surgical sperm recovery from men with non-obstructive azoospermia has become a routine part of clinical infertility practice, and as with the epididymis, cryopreservation of testis-derived spermatozoa has also become routine. A recent review concluded that surgical sperm recovery would be successful in some 48% of men with non-obstructive azoospermia. Undoubtedly one of the major problems confronting the process of surgical sperm recovery from men with non-obstructive azoospermia is the fact that there are currently

no good predictors of which patients will have sperm recovered successfully and which will not. Against this background, a number of groups have argued that surgical recovery of sperm from the testis coupled with cryopreservation should precede ovarian stimulation in the female partner.

For those men in whom mature spermatozoa cannot be recovered, there is currently interest in the possibility of using less mature cells, commonly elongating or round spermatids, to achieve fertilization. Work in animal models has suggested that this may be a viable approach and there are a number of clinical case reports in the literature. At the present time, however, uncertainties over the safety and efficacy of this approach confine its use to properly designed clinical trials.

ICSI has become well established as an effective form of treatment for couples with male factor infertility. In the last year for which data are available (2006), the UK's Human Fertilisation and Embryology Authority reported that 47% of 41,827 IVF cycles in the UK used ICSI. Given that ICSI is effective, is it also safe? The rapid development of microassisted conception techniques and the widespread use of ICSI in alleviating male infertility have raised concerns about the health of the offspring. ICSI, by directly injecting individual spermatozoa into a mature oocyte, bypasses the natural physiological processes of normal sperm selection, raising concerns over the potential risk of congenital malformations and genetic defects in children born after ICSI.

Without doubt, the most thorough and detailed follow-up studies of ICSI offspring have been those orchestrated by the Brussels group (Bonduelle et al 1999) who have undertaken a prospective follow-up study of 1987 children born after ICSI, aiming to compile data on karyotypes, congenital malformations, growth parameters and developmental milestones. It was found that 1.66% of karyotypes determined by prenatal diagnosis were abnormal *de novo* (nine each of autosomal and sex chromosomal aberrations) and 0.92% were inherited structural aberrations. Most of these were transmitted from the father. Forty-six major malformations (2.3%) were observed at birth. Seven malformations observed by prenatal ultrasound were terminated. Twenty-one (1.1%) stillbirths, including four with major malformations, occurred later than 20 weeks of pregnancy.

Several other large cohort studies have been reported, and as the database of ICSI offspring grows larger, the available evidence on the health of these offspring is generally reassuring (Leunens et al 2008). It is important, however, to appreciate the important role that genetic aetiology plays in the origins of much male subfertility and the ability of ICSI to promote the transgenerational transmission of genetic defects causing gametogenic failure. The significantly increased risk of chromosomal abnormalities in men with impaired semen quality is easily managed by the appropriate investigation and counselling which are required prior to treatment. It is less easy to be certain how to respond to the available evidence on microdeletions of the Y chromosome in men with severely impaired semen quality. The strength of the association between Y chromosome deletions and severely impaired semen quality is impressive, and it is increasingly suggested that these lesions may result in progression from oligozoospermia to azoospermia over time. It is also clear that these genetic deletions, if present, can be

transmitted to offspring via ICSI. On the basis of this evidence, some authorities now advocate screening of men for Y chromosome microdeletions prior to ICSI, and advocate testing of offspring and reproductive monitoring for those found to have inherited deletions.

Changes in Male Reproductive Health

During the past two decades, a number of reports have raised serious concerns about the development of reproductive problems in animals and man. There have been controversial reports of changes in human semen quality (Carlsen et al 1992, Auger et al 1995, Irvine 1996), alongside reports of an increasing incidence of congenital malformations of the male genital tract, such as cryptorchidism and hypospadias (Kallen et al 1986, Ansell 1992) and of an increasing incidence of testicular cancer (Adami et al 1994, Wanderas et al 1995). However, there is controversy over whether or not these reported changes in male reproductive health are genuine, and if so, the causes and implications.

Testicular cancer

Although many of the changes seen in male reproductive health are controversial, there seems little argument that testicular cancer is increasing in frequency, with unexplained increases in the age-standardized incidence being observed in Europe (Adami et al 1994, Bergstrom et al 1996) and the USA (Devesa et al 1995). There would appear to be substantial geographical variation in both the incidence of testicular cancer and in the observed rate of increase (Adami et al 1994). Of note, this geographical variation may be linked with that seen in semen quality; testicular cancer is four times more common in Denmark, where studies have revealed rather low sperm counts (Jensen et al 1996), than in Finland, where semen quality appears to be better (Vierula et al 1996). Interestingly, the observed increases, both in Europe and the USA, would appear to be birth cohort related. Bergstrom et al (1996) evaluated data from Denmark, Norway, Sweden, East Germany, Finland and Poland, including data on over 30,000 cases of testicular cancer from 1945 to 1989 in men aged 20–84 years. They found considerable regional variation in both the incidence of testicular cancer and the observed rate of increase, ranging from a 2.3% increase annually in Sweden to a 5.2% increase annually in East Germany. In all six countries, birth cohort was a stronger determinant of testicular cancer risk than calendar time, such that men born in 1965 had a risk of testicular cancer that was 3.9 times [95% confidence interval (CI) 2.7–5.6; Sweden] to 11.4 times (95% CI 8.3–15.5; East Germany) higher than that for men born in 1905.

A recent study has looked in detail at the risk of testicular cancer in subfertile men (Moller and Skakkebaek 1999) using a population-based case-control design. This study found that paternity was associated with a reduced risk of testicular cancer (relative risk 0.63, 95% CI 0.47–0.85), and that prior to the diagnosis of testicular cancer, cases tended to have fewer children than expected for their age (relative risk 1.98, 95% CI 1.43–2.75). The study suggested that these observations are consistent with the hypothesis that testicular cancer and male subfertility share important aetiological factors.

Cryptorchidism and congenital malformations of the male genital tract

The incidence of congenital malformation of the male genital tract may also be changing, with increases observed in the prevalence of cryptorchidism and hypospadias. Cryptorchidism, for example, has increased by as much as 65–77% over recent decades in the UK (Ansell 1992). In contrast, some data from the USA have tended to suggest that rates of cryptorchidism have not changed (Berkowitz et al 1993), although one recent large study from the USA reported that rates of hypospadias doubled from the 1970s to the 1980s (Paulozzi et al 1997). Here too, though, regional differences have been observed, although the data are perhaps less robust than is the case with testicular cancer. One multicentre study of 8122 boys from seven malformation surveillance systems around the world concluded that, even when differences in ascertainment were taken into account, true geographical differences exist in the prevalence of hypospadias at birth (Kallen et al 1986).

Changing semen quality: historical data on normal men

In 1992, Carlsen et al (1992) reawakened concern over the possibility of secular trends in semen quality, publishing a meta-analysis of data on semen quality in normal men. The authors undertook a systematic review of available data on semen quality in normal men, published since 1930. Standard techniques applicable to meta-analysis were used to identify relevant papers, and care was taken to exclude data on infertile couples, men selected on the basis of their semen quality and data generated using non-classical approaches to semen analysis. Data were obtained on 14,947 men, published in 61 papers between 1938 and 1990. The authors observed a decline in sperm concentration from $113 \times 10^6/\text{ml}$ in 1940 to $66 \times 10^6/\text{ml}$ in 1990, along with a decline in the proportion of men with a sperm concentration above $100 \times 10^6/\text{ml}$. Predictably, the central message of this meta-analysis, that sperm counts had declined by approximately 50% over the past 50 years, attracted enormous attention and generated much controversy.

Since publication of Carlsen et al's meta-analysis, several papers have presented contemporary analyses of retrospective data. Unfortunately, the available data still fail to reach a conclusion on whether or not there is any secular trend in semen quality; at least as many studies have reported evidence of deteriorating semen quality as have reported evidence of no change. A very careful reanalysis of the historical data (Carlsen et al 1992) on semen quality in normal men (Swan et al 1997) found that there was evidence of a decline in sperm concentrations in the USA of $-1.5 \times 10^6/\text{ml}/\text{year}$ (95% CI -1.9 to -1.1), and in Europe of $-3.13 \times 10^6/\text{ml}/\text{year}$ (95% CI -4.96 to -1.30), but not in non-Western countries.

Whilst the available evidence is inconclusive and circumstantial, its weight is considerable and, at the very least, it should raise concerns that deserve to be addressed by properly designed, coordinated and funded research. Delay may compromise the fertility and reproductive health of future generations (de Kretser 1996, Irvine 1996).

KEY POINTS

1. The male partner should normally have two semen analyses performed during the initial investigation. Further investigations of the male partner should be preceded by a clinical examination including an assessment of secondary sexual characteristics and testicular size.
2. In considering the results of semen analysis for the individual couple, it is important to take into account the duration of infertility, the woman's age and the previous pregnancy history.
3. Sperm function tests are specialized tests and should not be used in routine investigation of the infertile couple.
4. Antioestrogens, androgens, bromocriptine and kinin-enhancing drugs have not been shown to be effective in the treatment of men with abnormalities of semen quality. The use of systemic corticosteroids for treatment of antisperm antibodies can only be recommended in the context of further research, as the evidence of benefit is conflicting and there are potentially serious side-effects.
5. Where a diagnosis of hypogonadotrophic hypogonadism is made in the male partner, the use of gonadotrophins is an effective fertility treatment.
6. Prior to treatment by ICSI, couples should undergo appropriate investigations including the male partner's karyotype, both to establish a diagnosis and to enable informed discussion about the implications of treatment.
7. Testing for Y chromosome microdeletions should not be regarded as a routine investigation prior to ICSI. However, it is likely that a significant proportion of male infertility results from abnormalities of genes on the Y chromosome.

Introduction

Regardless of the cause of infertility, assisted reproduction treatment (ART) offers the highest pregnancy rates per cycle among all the fertility treatment options, and is therefore being used increasingly worldwide. ART involves interventions manipulating gametes to enhance fertilization and subsequent occurrence of pregnancy, and includes in-vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), transfer of cryopreserved embryos, and treatment using donor gametes and embryos. More recently, GIFT and ZIFT have become less popular as the success rates are inferior to IVF and more invasive.

Since the first successful birth following IVF in 1978, there have been considerable advances in the field of ART and more than 3 million babies have been born across the world. ART is now widely available, and in a single year (2004), more than 360,000 treatment cycles were carried out in Europe. In the UK, a total of 44,275 IVF/micromanipulation and frozen embryo replacement (FER) cycles were reported in 2006, resulting in 12,596 livebirth events (Human Fertilisation and Embryology Authority 2008). The number of conventional IVF cycles remained reasonably steady between 1998 and 2008, while the number of ICSI treatment cycles has been increasing steadily since its introduction (Figure 22.1) Human Fertilisation and Embryology Authority 2008).

The Human Fertilisation and Embryology Authority (HFEA) was established in 1991 by the Human Fertilisation and Embryology Act 1990 to regulate and inspect all UK clinics providing ART, and was the first statutory body of its

kind in the world. The introduction of guidelines into clinical practice in general and in assisted reproduction in particular has led to an ever-increasing role for an evidence-based approach to the provision of these services. Clinical guidelines for the assessment and treatment of people with fertility problems have been published by the National Institute for Clinical Excellence (2004) to streamline services and avoid unnecessary waste of resources. This chapter will review the current status of conventional IVF, ICSI and other treatments, new developments in ART and the clinical risks associated with these techniques. The obstetric and neonatal consequences of these treatments and, in particular, the impact of the number of embryos transferred on the outcome will be discussed.

Selection and Evaluation of Patients

Although IVF was initially introduced to bypass tubal blockage, the currently available techniques enable the treatment of various causes of infertility. The current indications are shown in Box 22.1.

Emphasis should be placed on the pretreatment evaluation of the individual or couple, both medically and psychologically. Assessment of the welfare of the child that may result from ART, including its need for a positive male role model, has become central to the provision of treatment in the eyes of the HFEA. With that in mind, there should be careful consideration of the duration and stability of the couple's relationship, their medical and social backgrounds, and other relevant issues. In addition, information-giving and decision-making aspects of counselling should be made available by a specially trained counsellor as a matter of

Figure 22.1 Number of treatment cycles 1991–2006.

Box 22.1 Indications for IVF treatment

- Tubal disease
- Unexplained infertility
- Treated endometriosis
- Male factor infertility
- Failed artificial insemination by donor
- Failed ovulation induction
- Absent or inappropriate ovaries
- IVF in association with preimplantation genetic diagnosis (PDG)
- Fertility preservation for cancer patients and social reasons
- Treatment of single women and same-sex couples

routine to all couples. Couples should be interviewed together, and appropriate history and clinical examination should be undertaken for both partners. For the female partner, baseline hormone profile, mid-luteal-phase progesterone assay and rubella status must be determined. Additional tests such as thyroid function, high vaginal or endocervical swabs, and cytomegalovirus status should be performed where necessary. Hepatitis B and C and human immunodeficiency virus screening are mandatory in the UK for both partners before ART.

Evaluation of pelvis

Ultrasound evaluation of the pelvis is often performed prior to ART to rule out any adnexal and uterine pathologies, such as polycystic ovary syndrome (PCOS), endometriosis, tubal disease, fibroids and endometrial polyps, which are clearly associated with aberrant and compromised outcomes during IVF.

The diagnosis of PCOS is currently based on the definition derived by the Rotterdam Consensus Workshop, which suggested the presence of 12 or more follicles measuring 2–9 mm in diameter and/or an ovarian volume of more than

10 cm³ for the ultrasound diagnosis (Balen et al 2003). Stromal vascularity and blood flow velocities are higher in women with polycystic ovaries (Agrawal et al 1998), and this may account for their tendency towards ovarian hyperstimulation in response to gonadotrophin therapy.

Endometriosis has been shown to have a negative effect on the outcome of ART, with affected women demonstrating a reduced response to ovarian stimulation (Gupta et al 2006); however, reports on its effects on embryo quality and implantation potential are conflicting. Moderate and severe degrees of endometriosis, often characterized by rectovaginal disease and the presence of ovarian endometrioma, can usually be diagnosed by transvaginal ultrasound (Moore et al 2002).

The presence of a hydrosalpinx is associated with poor implantation and pregnancy rates, and early pregnancy loss. The exact mechanism is unknown but substances toxic to the endometrium are thought to be produced that have a negative effect on endometrial receptivity (Strandell 2007). Salpingectomy, ideally performed laparoscopically, prior to IVF has been shown to be beneficial and is recommended. The diagnosis of hydrosalpinx can generally be made using transvaginal ultrasound with a high degree of confidence.

Ultrasound assessment of the uterus is generally restricted to measurement of the endometrial thickness and a description of the locality and size of any fibroids. Conventional ultrasound may also detect uterine anomalies, although these are more readily identified and correctly qualified with three-dimensional ultrasound. The diagnosis of uterine anomalies is important as they are associated with lower implantation rates and increased rates of early miscarriage, preterm labour and malpresentations (Lin 2004). The outcome appears to relate more to the length of the remaining uterine cavity than the degree of septum, and this may be measured reliably with three-dimensional ultrasound (Salim et al 2003).

The diagnosis and classification of fibroids into subserosal, intramural and submucosal is usually straightforward, and this is important as these have a progressively negative effect

on pregnancy rates. Whilst intramural fibroids measuring more than 4 cm in diameter and submucous fibroids of any size are thought to have a negative effect on the outcome of fertility treatment and to be associated with lower pregnancy rates, the effect of smaller intramural fibroids on reproductive outcome is unclear (Oliveira et al 2004). There is also doubt about the exact impact of endometrial polyps, the other commonly encountered intrauterine pathology, on treatment outcome and early pregnancy. Some authors suggest conservative management, especially if the polyp is small (Isikoglu et al 2006), but this can be difficult in patients undergoing fertility treatment or with a history of miscarriage when a polyp is identified before treatment begins. Polyps are usually evident with conventional transvaginal imaging, although false-positive diagnoses are common. Saline infusion sonohysterography can reduce this and facilitate appropriate operative planning (Bartkowiak et al 2006). Delineation of the polyp with saline ensures that the size and position of the polyp can be defined accurately, allowing surgeons to modify their approach and resect the larger, more broad-based polyps rather than planning for simple polypectomy. Hysteroscopy is the gold standard technique for uterine cavity assessment, and may be necessary if diagnosis of intrauterine pathologies is in doubt.

Assessment of ovarian reserve

Evaluation of ovarian reserve has become an integral part of the pretreatment assessment of a woman about to undergo ART, and is recommended for all women planning ART (Speroff and Fritz 2005). The aim is to identify women likely to respond poorly, those who have a low chance of success and who are more likely to have their treatment cycle cancelled, and those prone to ovarian hyperstimulation which is associated with significant morbidity and even mortality. Accurate assessment of ovarian reserve and prediction of response therefore facilitates pretreatment counselling of couples of their potential risks, and allows treatment to be tailored to the individual, potentially increasing the number of oocytes retrieved without risking an exaggerated response. Ovarian reserve, defined by the size and quality of the remaining ovarian follicular pool at any given time, reflects the fertility potential of a woman (Broekmans et al 2006).

Although women's age is an important predictor of ovarian reserve and response, a great deal of interindividual variation exists, even among women of the same age (te Velde and Pearson 2002). This is indicative of a wide variation in the rate of age-related decline in the ovarian follicle population. Several endocrine and ultrasound markers have been reported, with the aim of estimating the number of gonadotrophin-responsive or 'selectable follicles' more accurately. The endocrine markers include factors produced by the developing follicles [oestradiol, inhibin B and anti-Müllerian hormone (AMH)] or hormones under the inhibitory control of these factors [follicle-stimulating hormone (FSH)]. The ultrasound markers are antral follicle count, ovarian volume and ovarian vascularity. The sensitivities, specificities and predictive values of these tests have been evaluated in many studies by correlating the test results with the number of oocytes retrieved, poor or exaggerated ovarian response, and pregnancy or livebirth rates during ART (Broekmans et al 2006).

Serum follicle-stimulating hormone

Early-follicular-phase FSH is the most widely used marker of ovarian reserve, and women with raised FSH levels (>10–15 IU/l) are more likely to have a reduced ovarian response and less successful ART outcome (Scott et al 1989, Sharif et al 1998). A meta-analysis of 21 studies looking at the value of basal FSH in the prediction of IVF outcome concluded that the performance of basal FSH as a screening test is limited in predicting poor ovarian response and non-pregnancy. Predictions with a substantial shift from pre-FSH-test probability to post-FSH-test probability are only achieved at extremely high cut-off levels (Bancsi et al 2003). Moreover, the cycle-to-cycle variability of basal FSH levels limits the reliability of a single measurement for assessment of ovarian reserve. However, it is important to note that ovarian response and pregnancy rates during IVF are low in women with high intercycle variability (Scott et al 1990) or who demonstrate abnormal FSH levels in any menstrual cycle (Abdalla and Thum 2006).

Oestradiol

Measurement of basal oestradiol in addition to FSH is recommended to improve predictive accuracy. Premature elevation of the oestradiol level due to advanced follicular development and early selection of a dominant follicle may tend to suppress the FSH level, thus masking a rise that might otherwise reflect a low ovarian reserve (Frattarelli et al 2000). An elevated level of basal oestradiol (≥ 60 pg/ml), even in the presence of a normal FSH level, is associated with increased risk of cycle cancellation due to poor ovarian response (Evers et al 1998). However, the use of serum oestradiol estimation for ovarian reserve assessment is limited by the fact that some women with a normal ovarian reserve may have an occasional accelerated cycle with FSH levels of mid-follicular range in their true early-follicular phase (Frattarelli et al 2000). Furthermore, elevated oestrogen may simply reflect the presence of functional ovarian cysts.

Inhibin B

Inhibin B is principally produced by the granulosa cells of the developing cohort of antral follicles during the luteal–follicular transition. Its level in the early-follicular phase is considered to be indicative of the quantity or quality of developing follicles (Hall et al 1999). A low level (<45 pg/ml) of early-follicular-phase inhibin B may predict a poor ovarian response (Seifer et al 1997). However, the reliability of its measurement has been questioned because of significant intercycle variability (McIlveen et al 2007).

Anti-Müllerian hormone

Studies have shown that AMH is a promising serum marker of ovarian reserve (van Rooij et al 2002). AMH, a member of the transforming growth factor- β family of growth and differentiation factors, is primarily produced by the preantral and small antral follicles in women of reproductive age. The serum level of AMH is indicative of the growing follicle pool (de Vet et al 2002). While AMH is highly predictive of poten-

tial poor or exaggerated responders to ovarian stimulation during ART, its accuracy to predict the occurrence of pregnancy after one cycle of ART is only marginal (Broekmans et al 2008). Recent studies have suggested that AMH levels vary minimally between menstrual cycles and are cycle independent (Fanchin et al 2005, La Marca et al 2006). Therefore, AMH measurement could be undertaken during any cycle and at any time during the cycle for adequate prediction of ovarian response, and this makes it an attractive marker for routine use. However, there are potential limitations to the regular use of AMH as a marker of ovarian reserve because of different cut-off levels reported in different studies. Currently, there is no international assay standard for AMH measurement, which may contribute to the discordance between different studies and make comparison between laboratories quite difficult. Once the available assays are standardized and automated analysis systems are developed, AMH has the potential to become the test of choice for ovarian reserve.

Dynamic ovarian reserve tests

Dynamic tests have also been reported for the assessment of ovarian reserve. Dynamic testing is a provocative test of ovarian reserve that examines the endocrine dynamics of the menstrual cycle which change with the functional activity of the remaining follicles within the ovary. This involves the measurement of an endocrine marker of ovarian reserve (FSH or oestradiol) both before and after ovarian stimulation using clomiphene, gonadotrophin-releasing hormone (GnRH) agonist or FSH. The literature suggests that none of these tests offer any more predictive information than the previously described tests. Moreover, the inconvenience, expense and potential side-effects associated with the use of the additional pharmacological agents limit their use for pretreatment assessment of ovarian reserve.

Antral follicle count

Antral follicle count (AFC) is the most significant predictor of ovarian response among the ultrasound markers (Kwee et al 2007, Jayaprakasan et al 2009), although decreased ovarian volume ($<3 \text{ cm}^3$) and stromal blood flow are also implicated for poor treatment outcome during ART. The number of gonadotrophin-responsive antral follicles measuring 2–10 mm can be measured using two- or three-dimensional ultrasound with an acceptably high level of agreement both between and within observers (Jayaprakasan et al 2008a). A total follicle count of between seven and 22 is generally considered as the optimum cut-off level for the prediction of poor and exaggerated ovarian response, respectively. AFC measurement can be performed either in the early-follicular phase of the cycle before treatment begins or after downregulation with similar predictive accuracy (Jayaprakasan et al 2008b). However, assessment prior to treatment has an additional advantage in that it provides an opportunity for pretreatment evaluation of the pelvis to screen for pathology. AFC and AMH are currently the best two predictors of ovarian reserve among all the endocrine and ultrasound markers, and are equally predictive of poor ovarian response during ART (Jayaprakasan et al 2010). AFC

is currently the test of choice for ovarian reserve assessment as it is easy to perform and due to inherent availability of ultrasound machines.

Ovarian reserve tests including AFC and AMH have limited value in the prediction of non-conception despite their adequate capacity to predict ovarian response during ART (Broekmans et al 2006). Pregnancy may occur even at extreme cut-offs for an abnormal test result; therefore, IVF treatment cannot be denied based on these tests, especially in participants who are seeking their first cycle of treatment (Broekmans et al 2007). However, the identification of participants who are likely to respond poorly during IVF treatment is clinically relevant, as a couple can be counselled accordingly. They can be made aware that they have an increased chance of cycle cancellation and a significantly lower chance of success, allowing an informed decision to be made. Such prediction also allows clinicians to formulate individualized treatment protocols to improve or at least maximize ovarian response.

Evaluation of male partner

The male partner should be evaluated carefully. Clinical examination, semen analysis including sperm function tests, genetic assessment and biochemical tests show that the aetiology of male subfertility can be divided into four main groups as follows.

- Primary spermatogenic failure, which is a testicular disorder resulting in the reduction of sperm count and abnormal sperm function. A number of different factors can induce this condition, including testicular maldescent, trauma, karyotype abnormalities, severe infection and antimetabolic therapy. However, in many patients, a cause cannot be ascertained.
- Congenital or acquired obstructive lesions. Men with failed reversal of vasectomy are increasingly seen in infertility clinics and, at present, constitute up to 10% of all male problems.
- Disturbances of erection or ejaculatory disorders, including those following spinal injuries.
- Endocrine disorders, such as Cushing's disease, thyroid disorders and androgen receptor abnormalities.

Many causes of male infertility may have considerable congenital implications for the children of such patients. Sixty percent of men with congenital bilateral absence of the vas deferens were shown to have one or more of the cystic fibrosis genes. The use of ICSI in these circumstances should be considered carefully, and men must be screened with the appropriate tests before treatment.

In order to give adequate counselling to couples and their families, genetic tests should be performed before, during or after ART in cases such as women with Turner's syndrome, men with 47XXY, men or women with structural chromosomal aberrations, and men with either Yq11 deletion or congenital bilateral absence of the vas deferens (ESHRE Capri Workshop Group 2000).

The couple must be well informed about the treatment options that are suitable for them, the indications for the tests they have to undergo, details of the proposed treatment and its success rate, and risks and complications.

Clinical Management of the Treatment Cycle

The first successful birth from IVF-embryo transfer (ET) in 1978 resulted from a single oocyte obtained from the dominant follicle in a natural ovarian cycle. Success rates were found to be improved when multiple embryos were available, allowing competitive selection of the best-quality embryo/s for transfer; thus, at present, the majority of assisted reproduction programmes undertake controlled ovarian stimulation to induce multiple follicular development and subsequently to obtain many fertilizable oocytes.

The main components of typical conventional ART include:

- pituitary downregulation using GnRH analogues;
- controlled ovarian stimulation using gonadotrophins;
- monitoring follicular development using transvaginal ultrasound with or without serum oestradiol levels;
- oocyte maturation using human chorionic gonadotrophin (hCG);
- egg collection and sperm production or sperm recovery;
- fertilization (IVF/ICSI) and subsequent embryo culture;
- fresh ET into the uterus and cryopreservation of surplus good-quality embryos; and
- luteal support by progesterone administration.

Normal folliculogenesis

This involves several important and inter-related steps.

- **Follicular recruitment.** This occupies the first few days of the ovarian cycle and allows the follicle to continue to mature in the correct gonadotrophic environment and to progress towards ovulation.
- **Selection.** The mechanism whereby a single follicle is chosen and ultimately achieves ovulation.
- **Dominance.** The selected follicle maintains its pre-eminence over all other follicles and occupies days 8–12 of the primate ovarian cycle.

Follicular development beyond the antral stage depends on the concentration of FSH in the circulation. Once a threshold level has been attained, follicular growth beyond 4 mm occurs. The interval during which FSH remains elevated above the threshold level can be regarded as a window through which a follicle must pass to avoid atresia. The width of the window will therefore determine the number of follicles that can be selected for ovulation (Figure 22.2). The preovulatory luteinizing hormone (LH) surge is triggered by the positive feedback of oestradiol from the dominant follicle, as well as other follicular contributory factors. Ovulation occurs 24–36 h after the onset of the LH surge.

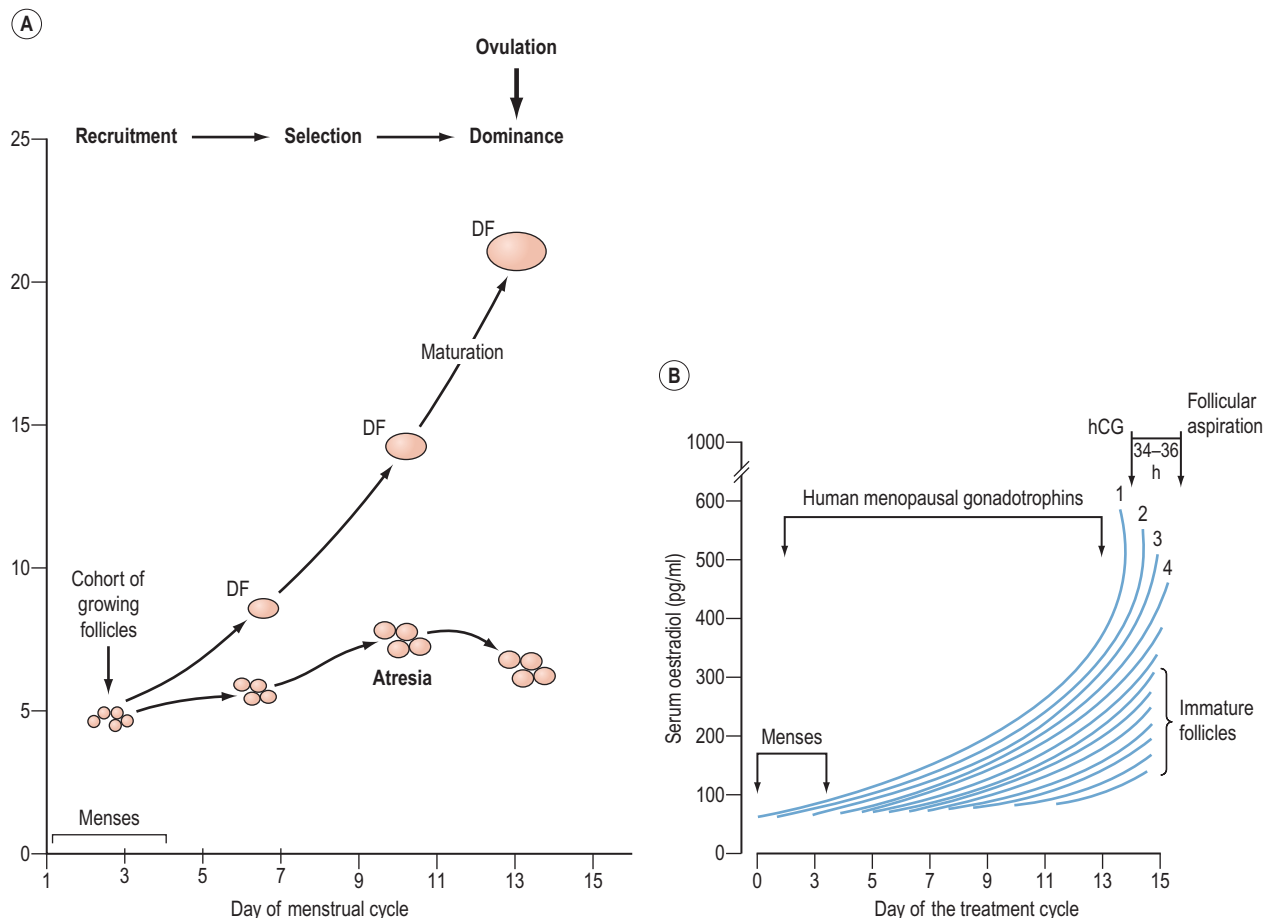

Figure 22.2 (A) Selection and maturation of the dominant follicle (DF) during a natural cycle. (B) Induced follicle maturation with gonadotrophin therapy over-riding selection of a single dominant follicle, as in the natural cycle. hCG, human chorionic gonadotrophin.

Pituitary downregulation

In the conventional ART protocol, it is standard practice to use a continuous and supraphysiological dose of GnRH agonist to obtain control over the hypothalamic–pituitary–ovarian axis. GnRH agonists cause an initial flare response, characterized by increased gonadotrophin secretion, due to upregulation of GnRH receptors. However, prolonged administration of GnRH agonists induces downregulation of GnRH receptors. This prevents a premature surge in LH and subsequent spontaneous ovulation with luteinization, which occurs in up to 23% of cycles when gonadotrophins alone are used and facilitates the timing of oocyte retrieval. The use of GnRH agonists in ART has been shown to increase the number of oocytes retrieved, improve the pregnancy rate and significantly reduce the chance of cycle cancellation (Hughes et al 1992).

Two different GnRH agonist protocols are used in most assisted conception units: long and short protocols. In the long protocol, GnRH agonists (buserelin or nafarelin) are started in the mid-luteal phase (day 21) of the previous menstrual cycle to achieve pituitary downregulation in approximately 8–21 days, after which gonadotrophins are commenced. GnRH agonists are administered for approximately 10–14 days in the short protocol. In both regimens, GnRH agonists are administered daily until the day of hCG or LH injection to trigger oocyte maturation. The short protocol takes advantage of the initial flare effect, which can be utilized to augment the ovarian response to gonadotrophin stimulation. However, a systematic review of 26 randomized-controlled trials found an increased clinical pregnancy rate per cycle and fewer cycle cancellations with the long protocol compared with the short protocol (Daya 2000). Therefore, the long GnRH agonist protocol is generally recommended in most ART cycles.

Use of the long GnRH agonist protocol often prolongs the stimulation phase, resulting in increased requirement for gonadotrophins and increased treatment cost in addition to causing undesirable side-effects of hypo-oestrogenism. It may also be associated with poor response in some patients, as well as introducing a higher risk of ovarian hyperstimulation syndrome (OHSS). Some of the disadvantages can be obviated with the use of GnRH antagonists, such as cetrorelix and ganirelix. GnRH antagonists induce immediate pituitary downregulation by competitively binding to GnRH receptors, and avoid the flare effects or the need for prolonged treatment associated with GnRH agonist protocols. Two different regimes have been described. The multiple-dose protocol involves the administration of 0.25 mg cetrorelix or ganirelix daily from day 6–7 of stimulation, or when the leading follicle is 14–15 mm, until hCG/LH administration. The single-dose protocol involves the single administration of 3 mg cetrorelix on day 7–8 of stimulation. GnRH antagonist protocols are therefore short and simple, but more importantly they reduce the incidence of severe OHSS. However, the clinical pregnancy rates following IVF treatment were significantly lower with GnRH antagonist use compared with the long GnRH agonist protocol [odds ratio (OR) 0.82, 95% confidence interval (CI) 0.68–0.97] (Al-Inany et al 2007), although data from units with experience of the GnRH antagonist protocol are encouraging. More recent trials of GnRH antagonists have reported better preg-

nancy rates than earlier trials, which used antagonist protocols that would now be recognized as suboptimal.

Controlled ovarian stimulation

The pregnancy rate with unstimulated IVF remains much lower than that in stimulated cycles, achieving a livebirth rate of 2.3% per initiated cycle and 4.7% per ET (Human Fertilisation and Embryology Authority 2000). These results have remained low over the past decade. Although an unstimulated cycle is simpler, faster, less painful, less expensive and has no risk of ovarian hyperstimulation, it requires relatively extensive monitoring which increases the cost and results in inconvenience in the timing of oocyte retrieval. Additionally, women with irregular cycles and/or hormonal imbalance or couples with male factor infertility, where fertilization may be a problem, are not suitable for natural-cycle IVF. The aims of superovulation regimens in assisted reproduction are to maximize the number of follicles that mature, to minimize the degree of asynchrony amongst developing follicles, and to minimize the deleterious effects of the abnormal follicular environment on luteal function and endometrial receptivity. Multiple follicular development and ovulation can be achieved by widening the FSH window. Several drug combinations have been used to achieve this.

Oocyte retrieval may be programmed to coincide with a working day by manipulating the onset of the menstrual cycle using norethisterone tablets, the combined oral contraceptive pill, or utilizing the hypogonadotrophic effect of GnRH agonists prior to commencing gonadotrophins on a predetermined day of the week. The downregulatory phase may be prolonged to allow a fixed number of patients to be treated each week. In the long GnRH agonist protocol, gonadotrophins are commenced following the confirmation of ovarian suppression, characterized by a thin endometrium of 5 mm less than transvaginal scan and a serum oestradiol level of less than 200 pmol/l.

The first commercially available gonadotrophin preparation used in superovulation protocols, human menopausal gonadotrophin (HMG), was extracted from the urine of menopausal women. The initial preparations were shown to be of low purity, and the major protein components were not gonadotrophins; only 5% constituted FSH and LH activity. The repeated injection of non-gonadotrophin proteins may be the cause of unwanted effects, such as pain and allergic reactions. The desirability for high-purity preparations led to the development of an immunopurified FSH product with more than 95% purity following the removal of LH activity from HMG. The introduction of highly purified urinary FSH was associated with much reduced hypersensitivity, enabling administration via the subcutaneous route. The currently available commercial preparation of HMG is also highly purified and contains both FSH and LH activity at a ratio of 1:1. The LH activity in HMG is partly due to the presence of exogenous hCG, which is added to correct imbalances in the FSH/LH ratio.

Genetic and molecular engineering has led to the production of recombinant human FSH (rFSH) with high purity (>99%), high specific bioactivity (>10,000 IU/mg protein) and absent intrinsic LH activity which is suitable for intramuscular or subcutaneous administration (Mannaerts et al

1991). Two different rFSH preparations are commercially available: follitropin alpha (Gonal F) and follitropin beta (Puregon). These two rFSH preparations differ in that follitropin alpha has a more acidic isoform profile than follitropin beta due to a slight difference in its carbohydrate component. Consequently, they differ in metabolic clearance, half-life and biological activity, but both are equally effective during ART cycles in terms of livebirth rates. A number of well-designed randomized-controlled trials have compared both preparations of rFSH against HMG in their clinical effectiveness during conventional IVF with the long GnRH agonist protocol. While none of them individually showed any statistically significant difference in livebirth rates between the two treatment arms, two recent systematic reviews have demonstrated a significant 4% increase in livebirth rate in the HMG arm (Al-Inany et al 2008, Coomarasamy et al 2008). However, the results of the meta-analysis need to be interpreted with caution because of the clinical heterogeneity of the trials; therefore, a large multicentre randomized double-blind trial is warranted. Moreover, such studies should consider reporting the more clinically relevant cumulative livebirth rates as the primary outcome.

Recombinant DNA technologies have also made it possible to produce LH (rLH). Due to the potential role of LH in follicular development according to the two-cell theory of gonadotrophin system, supplemental rLH has been suggested to improve IVF outcome if rFSH is used for ovarian stimulation. However, a recent systematic review of randomized trials failed to demonstrate any difference in livebirth rates with adding rLH to the rFSH protocol (Kolibanakis et al 2007). Although it is possible that rLH supplementation may be beneficial in a subset of the IVF population, such as poor responders (Mochtar et al 2007), its generalized use is currently limited.

The collective evidence from many studies suggests that 150–225 IU/day gonadotrophin is the appropriate starting dose for most women undergoing conventional IVF treatment. The majority of units use a daily dose according to women's age and the presence or absence of polycystic ovaries: 150 IU in women under 30 years of age or with polycystic ovaries, 225 IU for those between 30 and 39 years of age, and 300 IU for those aged 40 years or over. The lowest possible dose to achieve the optimum ovarian response should be used to reduce the risks of ovarian hyperstimulation. Although there is no consensus on what constitutes optimum ovarian stimulation, a recent study has reported that the implantation rate is maximum when 10 oocytes are retrieved following conventional IVF using the long down-regulation protocol (Verberg et al 2009a).

Recently, mild ovarian stimulation protocols have gained a lot of interest in the field of ART, with the current trend of limiting the number of embryos transferred reducing the need for large numbers of oocytes. The principal aim with this approach is to reduce the number of developing follicles and thereby minimize the adverse effects of ovarian stimulation, particularly OHSS and multiple pregnancies. Three reported mild stimulation protocols include clomiphene citrate alone or in combination with gonadotrophins, delayed commencement (day 5 of the cycle) of gonadotrophins with GnRH antagonist co-medication, and late follicular replacement of FSH with administration of hCG/LH (Verberg et al 2009b). All of these protocols have been shown to reduce the gonadotrophin dosage and have the

potential to reduce the cost of treatment and patient distress associated with conventional ART. As expected, the ongoing pregnancy rates/livebirth rates per cycle have been lower compared with the conventional protocol, but similar effectiveness could be achieved with more treatment cycles.

Monitoring follicular development

The purpose of monitoring ovarian response is to ensure safe practice in reducing the incidence and severity of OHSS, and also to optimize the timing of luteinization before oocyte retrieval. Ultrasound forms an integral part of monitoring. Follicular response together with endometrial thickness is monitored by ultrasound scans commencing on day 6–8 of the treatment cycle. Some units also measure serum oestradiol levels. However, current evidence does not support the adjuvant use of oestradiol for monitoring, as it does not give additional information with regard to livebirth rate or OHSS rate. The gonadotrophin dosage is adjusted according to ovarian response, although the evidence for this practice is limited. Typically, follicles are noted to grow at a rate of 2–3 mm/day, accompanied by a steady increase in serum oestradiol levels. When three or more follicles are 18 mm or greater in diameter, 5000–10,000 U hCG or 250 µg choriogonadotropin alpha (recombinant preparation) are given subcutaneously to induce oocyte maturation before oocyte retrieval.

Ovarian response is poor when no follicles or less than three follicles develop after 14 days of gonadotrophin treatment; this generally results in cancellation of the stimulation cycle. This problem is frequently encountered in women with reduced predicted ovarian reserve. Conversely, excessive ovarian response may result in OHSS, which will be discussed later. Other problems such as a premature LH surge or preoperative ovulation have been largely eliminated by the introduction of GnRH analogues in superovulation protocols.

Oocyte Retrieval

It is important to provide effective anaesthesia and analgesia for transvaginal oocyte recovery, as this is painful. No techniques for anaesthesia, analgesia or sedation are free from side-effects. Whichever technique is used, recognized standards of practice should be adhered to and all IVF professionals should follow the safe practice of administering sedative drugs published by the Academy of Medical Royal Colleges (2001). Conscious sedation should be offered to all women having the procedure as it is a safe and acceptable method of providing analgesia.

Equipment and preparation

Oocyte retrieval is performed 36 h after the trigger injection of hCG/LH. Methods of egg collection have improved considerably since the introduction of ART. At first, all egg collections were performed laparoscopically. This is now rarely used and is reserved for women whose ovaries are inaccessible through the transvaginal route. With the introduction of endovaginal transducers, the transvaginal-ultrasound-guided approach became the predominant method for egg collection. In this, the specially designed transducer is used

to visualize the follicles and the aspirating needle is passed alongside it. This method is generally well tolerated when carried out under light intravenous sedation, can be learnt very quickly and is associated with minimal morbidity.

Technique

Several types of aspiration needle are available. They may have a single or double lumen to enable aspiration and flushing through different routes. The needle is usually 16-gauge and must have a very sharp tip to enable easy puncture of mobile ovaries; the distal 2 cm should be roughened to enhance ultrasound visualization (Figure 22.3). The needle is connected to a test tube by tubing, and suction is applied either from a foot-operated pump (Figure 22.4) or manually. The ultrasound transducer (Figure 22.5) is enclosed in a special sterile condom and plastic sleeve prior to insertion into the vagina, and should be cleaned thoroughly with a damp cloth after each procedure.

Generally, very few technical difficulties are encountered during vaginal egg collection. The main risks of transvaginal oocyte recovery are pelvic infection (0.6%) and bleeding (>100 ml in 0.8% cases) (Bennett et al 1993), which may be serious, sometimes even fatal. Appropriate preoperative vaginal preparation and minimizing the number of repeated vaginal penetrations may serve to lower the risk of infection. While there is no evidence that routine antibiotics reduce the risk of infection, the administration of an intravenous bolus of antibiotic is generally recommended for women with a history of severe pelvic inflammatory disease or if an endometrioma is punctured. Intestinal, vascular, uterine and tubal injuries with the aspiration needle have also been

reported. Bleeding and infections may be serious, sometimes even fatal, complications.

Laboratory Techniques

The oocytes obtained are fertilized by conventional IVF or ICSI treatment dependent on the quality of the sperm obtained on the day of oocyte retrieval. ICSI is indicated if there is a severe deficit in sperm quality, obstructive or non-obstructive azoospermia, and for couples in whom a

previous IVF treatment cycle has resulted in failed or very poor fertilization. Sperm utilized for conventional IVF/ICSI is obtained by masturbation. When there is azoospermia, it is aspirated from the epididymis and/or testis, or extracted from the testes.

There are numerous techniques for performing the insemination of oocytes, and these vary from laboratory to laboratory. Differences in culture systems include the quantity and volume of sperm added to oocytes, culture of oocytes either singly or in groups, and open or oil-covered culture systems. IVF in the authors' unit is performed by incubating the collected oocytes in groups of five in a media drop of 150 μ l under oil; 22,500 sperm are added to this.

In cases of ICSI, meiotic maturity is assessed after denudation; only the mature oocytes are injected with sperm, following immobilization. Fertilization, as determined by the presence of two pronuclei, is assessed 18–20 h after insemination. On day 2 or 3, based on the cleavage rate, the size, shape, symmetry and cytoplasmic appearance of the blastomeres and the presence or absence of nucleus, embryo quality is graded by embryologists as grade 1, 2, 3 or 4 (Van Royen et al 1999). Grade 1 and 2 embryos are considered to be of high quality. While ET is performed with one or two of the best-available embryo/s, regardless of their grading, only top-quality (grade 1 and 2) embryos are considered eligible for freezing and this option is then offered to the couple.

Embryo Transfer

ET is a critical step in determining the final outcome of the treatment. The convention has been to replace embryos on the second or third day post insemination, when the embryos are usually at the two- to eight-cell stage of cleavage. With improvements in culture media, there is an increasing tendency for delaying ET with the aim of improving implantation rates. While there is no improvement in live-birth rates (OR 1.07, 95% CI 0.84–1.37) with delaying ET from day 2 to day 3 (Oatway et al 2004), transfer of embryos at the blastocyst stage (day 5/6) has shown a significant increase in the livebirth rate (OR 1.35, 95% CI 1.05–1.74) compared with transfers on day 2 or 3 (Blake et al 2007). It is a more physiological approach, allowing synchronization of the embryo with the endometrium, and selection of the viable embryos for transfer will be more efficient. However, the rates of embryo freezing are lower and the treatment cancellation rates are higher with blastocyst transfer. However, in certain couples, blastocyst transfer has the

Figure 22.6 Loaded embryo transfer catheter. One or two embryos are ready to be deposited within 1 cm of the uterine fundus.

Figure 22.7 Embryo transfer catheters. From top to bottom: trial Wallace catheter (no lumen), Wallace catheter, and outer sheath and stylet of malleable catheter.

potential to favour single ET without compromising the overall success rates, but can significantly reduce the occurrence of multiple pregnancies. The most favoured couples for blastocyst transfer are those with high numbers of eight-cell embryos on day 3, in whom cycle cancellation is not increased.

Transcervical embryo replacement into the uterine cavity is a relatively simple procedure, which must be carried out meticulously to ensure appropriate placement of the embryos (Figure 22.6). Variations among clinicians in the technique of ET may influence the pregnancy rate. Avoidance of blood, mucus, bacterial contamination, excessive uterine contractions and trauma to the endometrium is associated with optimal pregnancy and implantation rates after transcervical ET. Transabdominal ultrasonographic guidance to determine the precise depth of embryo placement within the uterus appears to facilitate successful ET and is preferred (Brown et al 2007), although a recent large randomized trial from a single centre did not show any benefit over 'clinical touch' transfer (Drakeley et al 2008). The tip of the catheter is placed approximately 1 cm from the uterine fundus so that the embryo/s are expelled gently into the mid-cavity of the uterus. Soft catheters are preferable to rigid catheters as they are less likely to traumatize the cervix or endometrium, or to invoke any uterine contractions. The commonly used soft catheters (Wallace catheters) (Figure 22.7) have a softer inner cannula and a stiffer outer sheath. Occasionally, resistance to pass the soft inner cannula into the uterus, usually at the level of internal os, is encountered; in these cases, the stiffer outer sheath is advanced into the cervical canal to negotiate the resistance, and the inner cannula can be advanced into the uterine cavity. A firmer malleable catheter

Figure 22.8 Livebirth rates per treatment cycle 1991–2005.

Source: Human Fertilisation and Embryology Authority (2008).

with a stylet and an outer sheath is another option in difficult cases, where the catheter is advanced up to the level of the internal os. The inner stylet is then removed and the softer cannula loaded with embryos is fed through the outer sheath to advance into the uterine cavity for transfer. The outer sheath or the malleable catheter should never be advanced beyond the internal os.

Following ET, women are often advised to continue their normal daily activities as prolonged bed rest has not been shown to improve IVF outcome. Luteal support is usually required as ART is associated with inadequate luteal function, possibly because of suppressed LH levels secondary to supraphysiological concentrations of oestradiol, removal of the granulosa cells surrounding the oocytes while performing the oocyte retrieval, and the use of GnRH agonists. hCG or progesterone is traditionally used to provide luteal support during conventional IVF cycles. However, the routine use of hCG is not recommended because of the increased likelihood of OHSS and no benefit over progesterone in terms of IVF success. Progesterone can be administered either 200–800 mg/day vaginally or 50–100 mg/day intramuscularly; this is continued for 14–16 days, when a pregnancy test is performed.

Outcome Measures and Factors Affecting Success Rate

Pregnancy and livebirth rates per treatment cycle for IVF and ICSI have steadily improved worldwide over the past decade. Figure 22.8 shows the improvement in the livebirth rate per treatment cycle in the UK between 1991 and 2005 (Human Fertilisation and Embryology Authority 2008). It is now widely accepted that when attempting to ascertain whether or not a treatment is required, it is essential that the time-specific or cycle-specific conception rate is used. Crude pregnancy rate per couple is almost meaningless. Pregnancy rate per cycle can also be misleading if limited to the first cycle or two, because the rate may fall in subsequent cycles. Thus, cumulative conception or cumulative livebirth rates have been used increasingly in reporting conventional and ART outcomes. Cumulative conception rates for some of the most common causes of infertility in the untreated population were compared with those in couples following treatment with conventional methods (Hull 1992). The results showed that in some conditions, such as ovulatory dysfunc-

tion, or in women being treated with donor insemination, the cumulative conception rate following conventional therapy is almost the same as in normal women. However, in other circumstances, such as salpingostomy for distal tubal occlusion or the use of high-dose glucocorticosteroids for seminal antisperm antibodies, the prognosis is worse and the cumulative conception rates are lower than that which can be expected in a single cycle of IVF treatment.

The effectiveness of infertility treatments (IVF, ICSI, egg and sperm donation, embryo donation) is dependent on a reasonable likelihood that embryos can be created in vitro, and then placed in the uterus with a reasonable expectation that implantation will occur. Many factors determine the outcome of treatment, such as patient selection, age, cause and duration of infertility, and the number of attempts that couples undergo. The decision to recommend ART should be based on the likelihood that a pregnancy will occur without treatment, the possibility that a less invasive form of treatment might be effective and the likely outcome of IVF treatment (National Institute for Clinical Excellence 2004). The likelihood of treatment-independent pregnancy depends on the woman's age, the cause and duration of infertility, and previous pregnancy history. In a retrospective study (Vardon et al 1995), the incidence of spontaneous treatment-independent pregnancy in couples enlisted on an IVF programme was reported to be 11% of couples with low fertility. The main difference from those in whom pregnancy did not occur was a shorter duration of infertility.

Success of ART is also dependent on where the provision of service takes place. It is clear from the HFEA annual reports that the outcome of treatment varies between small and large centres. When discussing the likelihood of birth following IVF treatment with any couple, it is essential to consider the factors that can affect the outcome significantly. These include female age, body mass index, cause and duration of infertility, previous pregnancy history, number of embryos replaced, availability of surplus embryos for cryopreservation and the number of previous treatment cycles. Such advice is particularly relevant and important in women over 40 years of age, in whom success rates are reduced considerably and the risk of miscarriage is increased.

Female age

The woman's age at the time of treatment is an important prognostic factor when the success of IVF is discussed with

any couple. The number of oocytes and, consequently, the number of embryos decline with age. However, the cleavage rate does not seem to alter in the same manner. The number of embryos replaced compounds the effect of age and embryo implantation rates on pregnancy rate. The total number of embryos available for replacement influences this further. When a larger number of embryos is available for replacement, the selection of the most appropriate embryos for transfer improves the implantation and pregnancy rates.

Indeed, when women over 40 years of age had four or more embryos transferred, their pregnancy rate was not significantly different from that of younger women, whether following IVF (Widra et al 1996) or ICSI (Alrayyes et al 1997). Hence, it may be concluded that older women with a good ovarian response, producing three or more embryos suitable for transfer, have similar prospects for establishing a pregnancy as younger patients. However, other data support reduced implantation rates in older women, regardless of the number of embryos transferred (Piette et al 1990). Younger women, even if their ovarian response is poor, have a better implantation rate than women over 40 years of age experiencing a normal ovarian response (van Rooij et al 2003). This indicates that age is the major determinant of the implantation potential of oocytes and/or of endometrial receptivity. However, the reported finding of similar pregnancy rates in older women having treatment using donor eggs compared with younger women indicates that oocyte quality or implantation potential, rather than endometrial receptivity, declines with women's age (Van Voorhis 2007).

Although livebirth rates per treatment cycle following IVF and ICSI have increased consistently over the past decade, they decline with advancing age of women when using their own eggs (Figure 22.9). A number of investigators have examined different age cut-offs such as 40 years (Widra et al 1996, Sharif et al 1998) or 35 years (Preutthipan et al 1996). Mardesic et al (1994) reported that the cut-off point of effectiveness for an IVF programme was 36–37 years, with a marked decline in pregnancy rate per ET in women over 38 years of age. In an attempt to identify factors that affect the outcome of treatment, Templeton et al (1996) analysed the HFEA database between 1991 and 1994. They reported that the overall livebirth rate per treatment cycle was 13.9%. The highest livebirth rates were in women aged 25–30 years, with younger women (<25 years) having lower rates, and a sharp decline noted in older women. At all ages over 30 years, the use of donor eggs was associated with significantly higher livebirth rates compared with the use of the women's own eggs, although there was equally a downward trend in

success rates with age. After adjustment for age, increasing duration of infertility was associated with a significant decrease in livebirth rates. The indications for treatment had no significant effect on the outcome, while previous pregnancy and live birth increased treatment success significantly.

Miscarriage rates have been reported to be higher in all women following IVF, and there is a two- to three-fold increase in the rate of spontaneous abortion in women aged 40 years or more (Toner and Flood 1993). Embryo quality is more likely to be the main factor influencing the poor reproductive performance of women with advancing age than a defective response of the uterine vasculature to steroids or uterine ageing. Increasing maternal age correlates with a higher risk of fetal chromosomal aneuploidy, which results in an increased rate of miscarriage (Spandorfer et al 2004).

Obesity

Although the consequences of obesity for women's fertility are well known, there is controversy regarding the effect of obesity on the outcome of IVF treatment. Overweight [body mass index (BMI) ≥ 25] and obesity (BMI ≥ 30) have been associated with the need for higher doses of gonadotrophins, increased cycle cancellation rates and retrieval of fewer oocytes. Lower rates of ET, pregnancy and live birth have also been reported, as have higher miscarriage rates (Fedorcsak et al 2004). Other studies have not found that obesity has a negative impact on ART outcome (Dechaud et al 2006, Sneed et al 2008). However, a recent systematic review of all the reported studies confirmed that obesity has an adverse effect on the success of IVF (Maheshwari et al 2007); therefore, obese women should be advised to lose weight before commencing ART in order to improve their chance of success.

Cause of infertility

Reports have differed in their analysis of the impact of infertility factors on cumulative conception and livebirth rates. While some have found significant differences, with the lowest rates being reported in patients with male infertility or multiple infertility factors (Tan et al 1992), others found no significant effect on outcome (Templeton et al 1996). However, a history of previous pregnancy and live birth increased treatment success significantly. The IVF clinical pregnancy and livebirth rates in the HFEA report of 2000

Figure 22.9 Livebirth rates by age of women who have in-vitro fertilization or intracytoplasmic injection. Success rates have improved over the years for all ages.
Source: Human Fertilisation and Embryology Authority (2008).

show similar results for tubal disease, endometriosis and unexplained infertility (Figure 22.10). Reports of higher fertilization rates after ICSI suggest that this technique may be better than the conventional method for all couples seeking IVF. A multicentre randomized-controlled trial comparing clinical outcome after ICSI or conventional IVF in couples with non-male-factor infertility showed higher implantation and pregnancy rates per cycle after IVF, hence supporting the practice of reserving ICSI for severe male factor infertility (Bhattacharya et al 2001).

All stages of endometriosis are viewed as suitable indications for ART. The timing of treatment is dependent on the severity of the disease, previous therapy and other factors, such as female age and duration of infertility. In women with severe endometriosis with mechanical tubal blockage and where surgery is inappropriate, IVF should be expedited. IVF should also be recommended 1–2 years after previous unsuccessful medical or surgical therapy, while in minimal or mild endometriosis, the balance of choice seems to be in favour of IVF after more than 2 years of expectant management. Initially, poor results were reported in women with severe disease (Matson and Yovich 1986). The introduction of ultrasound-guided techniques for oocyte collection resulted in the retrieval of more oocytes, and hence led to higher pregnancy and implantation rates in advanced-stage disease (Geber et al 1995). The use of GnRH agonists in stimulation protocols or as a pretreatment for women with endometriosis has also resulted in the retrieval and transfer of more preovulatory oocytes, lower cancellation of treatment cycles and a higher pregnancy rate, especially in women with advanced-stage disease. A recent meta-analysis indicated that the presence of ovarian endometrioma does not affect the quality of oocytes, as the pregnancy rate was similar to that of controls, although the ovarian response to gonadotrophins was reduced (Gupta et al 2006). While prospective randomized-controlled trials are lacking, evidence based on case-control studies suggests that surgery for bilateral endometrioma could impair IVF outcome significantly, possibly due to damage to the remaining healthy ovarian follicles (Somigliana et al 2008).

For male factor infertility, ICSI was successfully introduced in 1992 (Palermo et al 1992). Since then, the annual

number of treatment cycles has increased steadily (see Figure 22.1). Previous techniques, such as partial zona dissection and subzonal insemination, were very disappointing (Cohen et al 1991), and comparative studies indicated that ICSI was much more efficient (Tarin 1995). It gave men who had previously been diagnosed with severe male factor infertility the chance to have their own genetic children. The sperm may be obtained either by ejaculation, percutaneous aspiration from the epididymis or testis, or testicular extraction, resulting in equally high fertilization, pregnancy and implantation rates, especially in men with borderline or very poor sperm quality. Recognized indications for ICSI include:

- very poor sperm quality;
- obstructive azoospermia;
- non-obstructive azoospermia; and
- previously failed or very poor fertilization.

Livebirth rates following ICSI are shown in Figure 22.8. A remarkable change in fertilization rate with a significant increase in the percentage of two pronuclei oocytes occurred when the technique was modified slightly by breaking the sperm's tail before injection (Fishel et al 1995). The technique requires a high-quality inverted microscope and special equipment, with holding and injection pipettes being used to stabilize and inject the oocyte, respectively. The injecting pipette is pushed almost entirely through the ooplasm before the spermatozoon is deposited inside the oocyte (Figure 22.11).

Duration of infertility

The duration of infertility remains one of the most important variables that influences the outcome of assisted reproduction, with lower pregnancy and livebirth rates associated with a longer period of infertility. Analysis of the HFEA database between 1991 and 1994 showed that, even with adjustment for age, there was a significant decrease in livebirth rate with increasing duration of infertility from 1 to 12 years (Templeton et al 1996).

Source: Human Fertilisation and Embryology Authority (2000).

Figure 22.11 Intracytoplasmic injection of a single sperm (arrow) into the egg.

Endometrial thickness

Endometrial thickness alone is a poor predictor for pregnancy. However, no conception has been recorded for endometrial thickness below 5 mm on the day of transfer. As such, it is recommended that consideration should be given to cryopreserving all embryos and preparing the endometrium with exogenous hormones in a subsequent cycle (Friedler et al 1996).

Number of embryos transferred

Regarding the optimum number of embryos to be transferred, there is a great deal of debate and a wide variation in practice across the world. Unarguably, ART is the single most important cause for the increase in multiple pregnancies over the last two decades, which is a direct consequence of the number of embryos transferred. Retrospective studies, as early as 1985, argued that multiple pregnancies and births increased with the increase in the number of embryos replaced (Wood et al 1985). Randomized studies comparing double ET with treble ET (Staessen et al 1993) or quadruple ET (Vauthier-Brouzes et al 1994) reported similar pregnancy rates, provided that there were sufficient morphologically regular embryos available for transfer. Analysis of the HFEA database of more than 44,000 cycles (Templeton and Morris 1998) and the HFEA reports (2000) showed that when four or more fertilized eggs were available, the transfer of three embryos did not result in improved pregnancy rates compared with the elective transfer of two embryos. However, the incidence of triplets or higher order multiple births decreased considerably when two embryos were replaced (Figure 22.12).

Despite only transferring two embryos during most IVF cycles, 40% of all IVF babies are twins (Human Fertilisation and Embryology Authority 2008). In order to deal with the unacceptably high multiple birth rates following ART, there is a recent move from the IVF community, particularly in Europe, to limit the number of embryos transferred to one in carefully selected patients. In the UK, the HFEA has set a target of reducing the multiple pregnancy rate to 10% over a period of about 3 years, and has urged the fertility clinics to devise a 'multiple pregnancy minimization strategy' to achieve the agreed target. To facilitate this, the British Fertility Society in unison with the Association of Clinical Embryologists in the UK have produced guidelines for practice which focus on the effectiveness of elective single ET (eSET) and patient selection for eSET (Cutting et al 2008). The two most important criteria when choosing a couple for eSET are female age and the quality of embryos available. Twin pregnancy has increased risk for the fetuses and the mother. Given the higher risks of premature delivery (three-fold), perinatal mortality (six-fold), cerebral palsy (four- to six-fold) and pregnancy complications (hypertension, pre-eclampsia, gestational diabetes etc.), and the consequent resource implications for the health service with twin births compared with singleton deliveries, the HFEA in the UK has urged for successful IVF to be redefined as 'full-term singletons with a normal birth weight' in order to promote eSET and thereby reduce multiple births (Cutting et al 2008). A Cochrane review comparing the outcome of double ET in a single cycle compared with eSET (combined with transfer of

a single frozen-thawed embryo in a subsequent cycle if necessary) identified similar pregnancy rates in both groups (OR 1.19, 95% CI 0.87–1.62) with a substantially higher multiple pregnancy rate following double ET (OR 62.83, 95% CI 8.52–463.57) (Pandian et al 2005). Several European countries have now adopted eSET coupled with effective cryopreservation programmes in patients with a good prognosis, and have reported no significant difference in pregnancy rates but a significant reduction in the rate of twin pregnancies. In carefully selected patients (e.g. women <37 years of age, undergoing their first IVF cycle and with more than one top-quality embryo), eSET plus subsequent frozen embryo replacement can be as effective as double ET.

Number of attempts

The literature appears to be somewhat divided regarding pregnancy and livebirth rates in relation to the number of ART attempts. In one study (Padilla and Garcia 1989), the pregnancy rate per ET was similar for at least seven attempts, while other studies (Tan et al 1992, Templeton et al 1996) reported a decline in pregnancy and livebirth rates with successive treatment cycles. The data from the HFEA 2000 annual report show a steady decline in pregnancy and livebirth rates per cycle after the fifth attempt, being 11.1% and 8.6%, respectively, at the 11th attempt (Figure 22.13).

When IVF cumulative pregnancy rates were estimated for a cohort of women, the rates showed a constant rise during the six initial IVF treatments and plateaued subsequently (Dor et al 1996). Similarly, the rates were reported to be as high as 80% after seven cycles, and a history of previous pregnancy improved a couple's probability of conception significantly (Croucher et al 1998).

Embryo cryopreservation

The ability to cryopreserve embryos enables any supernumerary embryos to be stored for some time before subsequent replacement when fresh ET has failed or if further children are desired. Additionally, cryopreservation has the added benefit of increasing the number of potential embryo replacement cycles without the need to undergo superovula-

tion and oocyte retrieval, hence reducing the risk of OHSS. Embryo quality has the most significant impact on post-thaw survival and, ultimately, pregnancy and implantation rates. As with fresh embryos, factors such as female age, number of embryos transferred and whether a pregnancy resulted from the original stimulation cycle will affect the outcome of the FER cycle.

In 2005, the HFEA annual register reported a clinical pregnancy rate of 18% and a livebirth rate of 15.6% per FER cycle in women using their own gametes (Human Fertilisation and Embryology Authority 2008). Over the past decade, considerable improvement has taken place. The French register (FIVNAT 1996) reported an increase in pregnancy rate per transfer from 11.5% to 16% between 1987 and 1995. It has been estimated that one FER cycle increases the 'take-home baby' rate by 5% (Kahn et al 1993), while treatment involving one fresh and two FER cycles achieves a cumulative viable pregnancy rate of 41% (Horne et al 1997). Frozen-thawed embryos can be replaced in natural or hormonally adjusted cycles utilizing GnRH agonist and oestrogen/progestogen preparations with comparable results. The use of GnRH agonist is useful in anovulatory or irregular cycles, and the use of different progestogens for luteal-phase support is equally effective. The cost per delivery for an FER cycle has been estimated to be between 25% and 45% of the cost of a fresh cycle. In view of these advantages, cryopreservation should be accessible and discussed with all couples where surplus good-quality embryos are available.

Oocyte donation

Oocyte donation is an effective treatment for women with premature ovarian failure, Turner's syndrome, following oophorectomy, chemo- or radiotherapy-related ovarian failure, in certain cases where there is a high risk of transmitting a genetic disorder to the child, and where repeated failure of fertilization is attributed to poor oocyte quality. High pregnancy rates have been reported following oocyte donation for patients with Turner's syndrome (Khastgir et al 1997). However, Turner's patients were reported to have significantly higher biochemical pregnancy rates and early miscarriages, and lower clinical pregnancy and delivery rates compared with other women with premature ovarian failure (Yaron et al 1996). An important factor in the establishment

of pregnancy is an endometrial thickness of greater than 6.5 mm. Other factors include the number of previous natural conceptions and live births, and the fertilization rate, while increasing female age does not affect the outcome (Burton et al 1992).

The HFEA recommends that the age limit for egg donors should be 35 years, except in exceptional circumstances. This is because there is an increased pregnancy rate and reduced risk of aneuploidy in the offspring if the treatment is performed using eggs from young donors. Oocyte donors are screened for infections (human immunodeficiency virus, hepatitis B, hepatitis C and cytomegalovirus, Venereal Disease Research Laboratory tests for syphilis), genetic diseases such as cystic fibrosis, and major chromosomal anomalies. Targeted screening based on ethnic background is also recommended: for example, Tay-Sachs disease for Jewish population, sickle cell screening in Afro-Caribbean population and thalassaemia in Asian population. If the prospective donor is found to be heterozygous for cystic fibrosis, the partner of the recipient should also be screened for cystic fibrosis.

Oocyte donation has considerable emotional and social effects on both the donor and the recipient, more so if the donor is undergoing IVF treatment herself. Both the recipient and the donor should have counselling from someone who is independent of the treatment unit regarding the physical and psychological implications of treatment for themselves and their genetic children, including any potential children resulting from donated oocytes. Apart from anonymous and known oocyte donation, an egg share scheme is an efficient use of oocytes. This aims to reduce the imbalance between the large number of potential recipients and the small number of available donors. This also allows women requiring IVF and with insufficient funds for their own treatment to access IVF treatment for free or at a significantly reduced cost. Many studies have reported a safe 'cut-off' number of oocytes to be collected from the egg share donor to share with the recipient.

Livebirth rates following treatment using oocyte donation are excellent. Pregnancy and livebirth rates per treatment cycle following oocyte donation in comparison with other treatments are depicted in Figure 22.14 where fresh embryos are replaced, and in Figure 22.15 where frozen-thawed embryos are replaced (Human Fertilisation and Embryology Authority 2008). Neither the recipient's age nor the indication of treatment affects the success of oocyte donation substantially. However, pregnancy resulting from oocyte donation should be considered as high risk, especially in those with ovarian failure, because of an increased incidence of small-for-gestational-age infants. Oocyte recipients should also be counselled regarding their increased risk for pregnancy-induced hypertension and postpartum haemorrhage.

Health Risks Associated with Assisted Reproduction Treatment

Ectopic pregnancy

The first pregnancy following IVF was an ectopic pregnancy. There is a higher rate of ectopic pregnancy after IVF/ICSI treatment, principally due to the high prevalence of tubal

Figure 22.14 Clinical pregnancy and livebirth rates following in-vitro fertilization with fresh embryo-transfer-stimulated cycles, performed in 2005. Source: Human Fertilisation and Embryology Authority (2008).

Figure 22.15 Clinical pregnancy and livebirth rates following in-vitro fertilization with frozen embryo replacement, performed in 2005. Source: Human Fertilisation and Embryology Authority (2008).

factor infertility. The obstetric risks and outcomes of ART have always been the subject of considerable debate. Between 2% and 5% of ART pregnancies have been reported to be ectopic and 0.1–0.3% have been reported to be heterotopic (Clayton et al 2006). For comparison, the prevalence of ectopic pregnancy and heterotopic pregnancy following natural conception is approximately one in 100 and one in 30,000 respectively. The overall ectopic pregnancy rate per treatment cycle was 0.3% of over 467,778 IVF/ICSI cycles performed in the UK from 1991 to 2005 (Human Fertilisation and Embryology Authority 2008).

Ovarian hyperstimulation syndrome

OHSS remains the most serious and potentially lethal complication of ovarian hyperstimulation, correlates positively with conceptual cycles and is almost exclusively related to either exogenous or endogenous hCG stimulation. The pathophysiology of OHSS is characterized by increased capillary permeability, mediated by the vasoactive substances released from the hyperstimulated ovaries. Fluid leaks from the intravascular compartment into the third space, causing intravascular dehydration and, in severe cases, multisystem dysfunction. Young age, presence of PCOS, lean body mass and previous history of OHSS have all been reported to be risk factors for the development of OHSS. The risk increases with excessive ovarian response to gonadotrophins, characterized by the development of a large number of follicles including immature and intermediate follicles and/or high serum oestradiol levels. Mild forms are common, affecting

Figure 22.16 Vaginal ultrasound appearance of the hyperstimulated ovary. The enlarged ovary contains an excessive number of large, intermediate and small follicles.

up to 33% of IVF cycles. The overall prevalence of moderate-to-severe OHSS varies from 3% to 8% of IVF/ICSI cycles (Mathur et al 2007). The time of onset of OHSS may determine the prognosis; late-onset OHSS is likely to be more severe and to last longer than early-onset OHSS. Early-onset OHSS is due to the effects of exogenous hCG and presents within 9 days of the ovulatory trigger hCG. Endogenous hCG from an early pregnancy triggers the development of late-onset OHSS, which develops 9 days after the ovulatory hCG.

Prevention and early recognition are the two most important components in the management of OHSS. The key to prevention is proper identification of the population at risk before treatment, and close monitoring of hormone levels as well as follicular response on ultrasound (Figure 22.16). When a high-risk situation is recognized, withholding the ovulatory dose of hCG and cancellation of the treatment cycle will almost certainly prevent OHSS. The couple should be advised to avoid intercourse as spontaneous ovulation may occur up to 11 days after discontinuing gonadotrophin treatment, resulting in conception and development of severe OHSS.

Alternative strategies have been attempted and, when effective, they usually ameliorate the severity of OHSS rather than prevent it absolutely (see Box 22.2).

A diagnosis of OHSS is usually straightforward, with typical symptoms of abdominal distension, abdominal pain, nausea and vomiting, reduced urine output and breathing difficulties. Women with OHSS should have the severity of their condition assessed (RCOG 2006). Treatment of established OHSS depends on its severity, the stage at which the diagnosis is made and whether or not the patient is pregnant. In mild cases and most moderate cases of OHSS (haematocrit <45%), bed rest, simple analgesia, increased fluid intake and close monitoring of electrolyte balance may be sufficient. Women should be encouraged to drink to thirst, rather than to excess. The patient's progress can be supervised on an outpatient basis. Hospital admission should be recommended to some women with moderate OHSS and all those with severe OHSS (haematocrit ≥45%, massive ascites). Women should be kept under review until resolution of the condition. Inpatient management is mainly

Box 22.2 Alternative strategies to reduce the risk of OHSS

- Low starting dose of gonadotrophin in high-risk women has been attempted with varying degrees of success
- Use of GnRH antagonists for pituitary downregulation
- Reduction of the ovulatory hCG dose and avoiding its use in the luteal phase
- Triggering ovulation with GnRH agonist instead of hCG in GnRH antagonist cycles
- Metformin co-treatment during gonadotrophin stimulation in women with PCOS
- Use of intravenous albumin infusion
- Withholding hCG administration: cancel cycle

aimed towards preventing or alleviating haemoconcentration, renal hypoperfusion and thromboembolic phenomena. Initiation of intravenous fluid is not always necessary unless oral intake cannot maintain renal perfusion and function. Analgesics and antiemetics should be instituted for symptomatic relief, along with subcutaneous heparin for antithrombotic prophylaxis. Diuretics should not be used in women with oliguria secondary to a reduced blood volume and decreased renal perfusion, as they may worsen intravascular dehydration. Paracentesis may be necessary for symptomatic relief or failing renal function as it results in a dramatic improvement in clinical symptoms, diuresis and improved creatinine clearance (Aboulghar et al 1992). Multidisciplinary input including critical care may be required for women who develop severe complications such as severe ascites, liver or renal dysfunction, thromboembolism or adult respiratory distress syndrome.

Risk of genital and breast cancer

The potential risk of genital cancer from follicular stimulation has initiated considerable debate (Brinton 2007). While the results of earlier studies were alarming, subsequent studies with much longer follow-up periods and better designs showed reassuring results. In a cohort study of 12,193 women, Brinton et al (2004) reported no increased risk associated with clomiphene or gonadotrophin use among subjects who had been followed-up for a median of 18.8 years. Subsequent larger studies concentrating on the effect of exposure to drugs used during IVF rather than those prescribed in earlier times also reported reassuring results (Venn et al 1999, Klip et al 2003). However, the average follow-up period in these studies was only 6–7 years. Therefore, long-term follow-up data are needed to fully evaluate the risk of exposure to gonadotrophins during IVF. Moreover, appropriate control groups should be used to determine whether the link is causal, as it is difficult to distinguish the effect of fertility treatment from that of infertility *per se* on the development of malignancies.

It is well established that endometrial cancer is sensitive to oestrogen, which is produced excessively during ovarian hyperstimulation. Most smaller cohort studies have not found any association between the fertility drugs and endometrial cancer, but the follow-up period in these studies has been less than 10 years (Brinton 2007). In a larger series with an average of over 20 years of follow-up, a significant two-fold increase in endometrial cancer was associated with

ovulation induction agents (Modan et al 1998). However, this study evaluated women who had undergone fertility treatment between 1964 and 1974, and therefore these results cannot be extrapolated to modern-day IVF treatment.

Concerns relating to the effect of high oestrogen and progesterone levels on the potential risk for the development of breast cancer have also been expressed. A large cohort study of over 90,000 subjects showed no association between exposure to ART and breast cancer (Gauthier et al 2004).

In summary, the effects of ovulation induction agents currently used in ART on genital cancer risk are unclear. Considering that the treatment protocols, preparations and dosages used during IVF are relatively new, and women exposed to IVF are only beginning to reach the cancer age range, further follow-up studies are required in this area.

Risk of congenital anomalies and malignancy in the newborn

Since IVF and ICSI became common fertility treatment modalities, concerns have been raised regarding the risk of major congenital malformations in children born following these treatments. While the majority of studies have shown an increased risk of major anomalies compared with spontaneously conceived pregnancies, some studies have been reassuring. A recent meta-analysis of 25 studies concluded that there is a statistically significant increase (30–40%) in birth defects compared with background risk (Hansen et al 2005). The authors expressed this result in terms of the number needed to harm, which in this case equates to the number of children that need to be conceived by ART for one additional child to be born with a birth defect. Therefore, for an underlying prevalence of birth defects between 1% and 4% of all births, the number needed to harm is between 250 and 62 treatments. ICSI enabled men with severe oligospermia or azoospermia to pass their genes on to their own progeny; an event that may not have been possible a few years ago. This raises certain questions about the genetic constitution of any resulting pregnancies after ICSI. A 1.2-fold increased risk of major birth defects in children born after ICSI (95% CI 0.97–1.28) compared with IVF was noted in a systematic review of the reported studies (Lie et al 2005). Sons of infertile males with Y chromosome microdeletions and born following ICSI treatment may inherit the same abnormality and are likely to be infertile.

The increased risk of congenital malformations in ART children may largely be due to the underlying parental background, rather than the treatment techniques themselves. In a recent comparative study of malformation in children born to fertile (time to pregnancy interval of ≤ 12 months) and subfertile parents (time to pregnancy interval of > 12 months), the overall prevalence increased with increasing time to pregnancy. Compared with children in the fertile group, singletons born to infertile couples had a higher rate of congenital malformations regardless of whether they were conceived naturally (OR 1.20, 95% CI 1.07–1.35) or after infertility treatment (OR 1.39, 95% CI 1.23–1.57) (Zhu et al 2006).

There have been concerns regarding increased risk of rare imprinting disorders such as Beckwith–Wiedemann's syndrome and Angelman's syndrome in children following ART. However, the data are inconsistent, with some studies reporting increased frequency in ART children (Sutcliffe et al

2006) and other studies not finding any association (Bowdin et al 2007). Due to the rarity of these conditions, much larger studies are required for reliable detection of such associations.

Risk of malignancy in children

The issue of childhood cancer among children born after ART has been addressed in a few studies. An increased prevalence of retinoblastoma and Langerhan's histiocytosis among children born after ART in comparison with the general population has been reported in two separate studies (Moll et al 2003, Kallen et al 2005). However, the overall risk of cancer and the individual incidence of all other recorded cancers were no greater than that in the general population (Kallen et al 2005). As childhood cancers are rare, larger studies are required for reliable evaluation of any increase in risk amongst ART children.

In the context of pregnancy outcomes, the aim of ART should be a healthy singleton delivery at term. However, infertile couples may not share this target. They do not appreciate the risks associated with multiple pregnancy; indeed, between 67% and 90% of couples may desire a twin birth, while less than one-third of couples regard a single child as an ideal outcome. Increasing age or duration of infertility has been associated with greater desire for multiple births (Murdoch 1997). As discussed earlier in this chapter, an increased multiple pregnancy rate is a major reason for the increased adverse obstetric and perinatal outcomes associated with ART.

Obstetric and Perinatal Outcomes of Assisted Reproduction Treatment

Antenatal and intrapartum complications following assisted reproduction

Many studies have examined obstetric outcomes after fertility treatment. The risk of spontaneous miscarriage appears to be higher among ART pregnancies than among the general population. This comparison can be misleading as ART pregnancies are commonly under intense surveillance; losses from a very early stage of pregnancy are often carefully documented and reported, whereas miscarriage rates among natural conceptions are extremely difficult to measure and can be easily underestimated. However, a large prospective study with a meticulously chosen control group concluded that the risk of spontaneous abortion may be increased by 20–34% in ART pregnancies compared with natural pregnancies after adjusting for differences in maternal age and previous spontaneous abortion (Wang et al 2004). However, this increased risk may be as a result of infertility itself rather than due to ART, as there was no difference in miscarriage rates between patients who achieved pregnancy following any fertility treatment, including ART, and those who conceived naturally while waiting for fertility treatment (Pezeshki et al 2000).

Comparison of obstetric outcomes of IVF/ICSI pregnancies with matched normally conceived pregnancies showed a significantly increased incidence of premature delivery, intrauterine growth restriction, vaginal bleeding and hyper-

tension requiring hospitalization, pre-eclampsia and caesarean births (Halliday 2007). The increased obstetric risk can be attributed to the high rate of multiple pregnancies in most cases. However, the risk of a more complicated pregnancy was found to be increased even when the ART twin and singleton pregnancies were compared with spontaneously conceived twins and singletons, respectively, in two separate meta-analyses, even after the subjects were matched for maternal age (McDonald et al 2005a,b). A similar conclusion was drawn in another systematic review with similar objectives (Helmerhorst et al 2004).

Pregnancy following ICSI treatment has generated interest due to the additional risks involved with these pregnancies, such as the microinjection technique and the use of testicular or epididymal sperm. However, no significant difference in obstetric outcomes between IVF and ICSI pregnancies was noted, except for prematurity which was higher in IVF singletons (Ombelet et al 2005). Couples undergoing ICSI for severe male infertility (oligoasthenoteratozoospermia) have slightly reduced fertilization rates, but have similar rates of pregnancy loss and other obstetric outcomes as other couples undergoing ICSI and IVF for non-male-factor infertility (Mercan et al 1998).

Women who conceive following oocyte donation, especially those with a history of ovarian failure, should be considered as high risk. While the majority of oocyte recipients experience a favourable outcome, an increased rate of obstetric complications in these pregnancies has been reported by many investigators (Soderstrom-Anttila 2001). Pregnancy-induced hypertension appears to occur more often than expected, even among young recipients (Wiggins and Main 2005), and the caesarean section rate is high.

Embryo cryopreservation and obstetric outcome

Cryopreservation of embryos has no apparent negative effect on obstetric outcomes. The results were comparable in pregnancies following transfer of frozen embryos derived from IVF or ICSI. However, the frozen ICSI group showed a significantly higher miscarriage rate than the frozen conventional IVF patients in one study (Aytoz et al 1999).

Perinatal outcome of assisted reproduction pregnancies

It is widely accepted that the increased incidence of multiple pregnancies following ART accounts for a disproportionately large share of adverse perinatal outcomes, including the increased incidence of very low birth weight, low birth weight, perinatal and neonatal mortality, and infant death. The increased incidence of death and morbidity in twin pregnancies compared with singleton pregnancies has been attributed mainly to prematurity and to adverse outcomes associated with premature delivery, such as hyaline membrane disease, hypocalcaemia, hypoglycaemia, hyperbilirubinaemia, small for gestational age and low Apgar scores. Slotnick and Ortega (1996) suggested that monoamniotic multiple gestations may be increased in zona-manipulated cycles (ICSI, zona drilling, assisted hatching), and although all resulting monoamniotic pregnancies ended in live births, there was a high incidence of intrauterine discordance in

fetal growth. Even when compared with matched control spontaneous twin pregnancies, ART twin pregnancies had low birth weights and needed more neonatal intensive care (Helmerhorst et al 2004). However, twins conceived with IVF/ICSI have comparable perinatal mortality and morbidity rates to spontaneously conceived controls (McDonald et al 2005a).

Elimination of multiple pregnancies will not eliminate the increased risk of adverse perinatal outcomes in ART. While twins born from assisted conception are not significantly disadvantaged compared with spontaneous twin pregnancies, ART singletons have a worse perinatal outcome compared with other singletons (Helmerhorst et al 2004). Singletons born from ART are at risk for lower mean birth weight and small for gestational age. Perinatal mortality appears to be significantly higher, even after matching for maternal age, parity and infant gender. ICSI treatment does not appear to differ from conventional IVF when perinatal outcomes are compared. Retrospective comparison of births resulting from cryopreserved embryos with those after conventional IVF and fresh ET showed no difference in perinatal mortality between the two groups (Wada et al 1994).

Preimplantation Genetic Diagnosis/Screening

Preimplantation genetic diagnosis (PGD) has been developed as an alternative to prenatal diagnosis of chromosomal or sex-linked disorders in embryos formed through ART procedures. Preimplantation genetic screening (PGS) refers to the application of PGD in infertile couples undergoing conventional ART as an alternative to the traditional selection of embryos based on morphological criteria, which do not detect aneuploidy embryos that are non-viable or which could give rise to a viable but disabled child (Anderson and Pickering 2008). Aneuploid embryos most commonly result from fertilization of oocytes that are affected with meiotic non-disjunction, a common reason for age-related decline in oocyte quality. By detecting and avoiding the transfer of aneuploid embryos and only selecting euploid embryos for transfer, the success of ART cycles could potentially be improved. The application of PGD has also been extended to preimplantation human leukocyte antigen (HLA) matching to ensure the birth of HLA-identical offspring for stem cell transplantation therapy to siblings.

The procedure involves biopsy of a single cell from the human cleavage-stage embryo at around the eight-cell stage or from the blastocyst, followed by the application of a sensitive diagnostic technique to that cell. At present, biopsied polar bodies and/or blastomeres and/or trophoblast cells biopsied from blastocysts have been used, and pregnancies as well as healthy babies have resulted from biopsied and diagnosed embryos. The diagnostic technique, specific for the disorder being tested, may be the analysis of enzymes, chromosomes or a specific mutation in the DNA. If the cell shows no abnormality in the course of this analysis, the embryo is judged to be normal and is transferred to the mother to initiate pregnancy.

The enzyme approach has been disregarded, for the few genes studied, as it has been difficult to differentiate between maternal gene expression (mRNA inherited in the egg

cytoplasm) and embryonic gene expression in the early embryo (Braude et al 1989). However, the analysis of chromosomes using fluorescent in-situ hybridization and the analysis of specific gene sequences using sensitive polymerase chain reaction for sexing or detection of a specific gene mutation, such as cystic fibrosis, have been used successfully.

Analysis of the first and second polar bodies is an alternative to embryonic biopsy. As the polar bodies contain the genetic information from the oocyte, it is possible to diagnose maternally derived mutations, translocations and aneuploidy. Paternally derived chromosomal abnormalities will be missed by polar body biopsies. In cases of recessive disorders, polar body biopsies are helpful as they can provide information about the maternal contribution to the embryo. It may be difficult to achieve a reliable diagnosis even with embryo biopsy, with which mosaicism and/or uniparental disomies deriving from trisomies originating from female meiotic errors will be missed. With the expanding range of PGD indications, combined testing is required when testing for the causative gene, linked markers, HLA typing and aneuploidy in the same case. Therefore, single, double or even triple biopsies may be required in order to establish an accurate PGD (Kuliev and Verlinsky 2008). Sequential or simultaneous additional biopsy procedures have been shown to have no detrimental effect on embryo development (Cieslak-Janzen et al 2006).

PGS has been proposed to improve the IVF outcome in women of advanced age, and in those with a history of recurrent miscarriage, repeated implantation failure or severe male infertility, who are at risk for having increased proportions of aneuploid embryos. Most commonly, nine chromosomes (13, 14, 15, 16, 18, 21, 22, X and Y) are screened for aneuploidy. Although PGS has no adverse effect on embryo development, the current available evidence does not support its use outside the context of research. A meta-analysis of five prospective randomized-controlled trials evaluating the effect of PGS for the indication of advanced women's age has reported a significant reduction in ongoing pregnancy rates (OR 0.56, 95% CI 0.42–0.76) compared with controls (Mastenbroek et al 2008). While the studies evaluating the use of PGS for other indications mentioned above are limited, the early evidence suggests that PGS does not improve the outcome, even in patients with a good prognosis (young age) who are undergoing single ET (Staessen et al 2008). In conclusion, the available evidence does not support the use of PGS to improve livebirth rates or reduce miscarriage rates in ART cycles, particularly for women of advanced age.

Looking into the Future

ART has improved substantially over the last three decades, and many subfertile couples are now able to have children through its application. However, clinicians and researchers continue to strive to achieve the desired outcome, i.e. a single healthy baby, with minimal side-effects and this poses new challenges. It is tempting to speculate on the areas that are most likely to witness such developments over the next few years.

Recombinant gonadotrophin preparations are now well established in superovulation protocols. While these compounds are well tolerated and as effective as the urinary products, the associated risks of OHSS and multiple pregnancies and the need for daily parenteral administration of medications do not constitute the features of a patient-friendly procedure. Active investigations are ongoing to develop a number of molecules with gonadotrophin-like activity. Longer-acting forms and orally bioactive preparations may revolutionize IVF treatment in the near future. Additionally, the use of mild ovarian stimulation protocols with a single ET policy may become the norm, leading to IVF treatment that is less drug-orientated.

Improving pregnancy and livebirth rates will remain a challenge for the future. Molecular cytogenetic procedures on polar bodies or blastomeres have indicated that more than 50% of embryos derived after ART are aneuploid. Elective transfer of euploid or top-quality embryo(s) increases the chance of a successful outcome. Currently, the embryos are scored based on morphology, but this is notoriously difficult and often subjective. Available evidence does not support the use of more invasive PGS techniques to improve livebirth rates following ART, and therefore more accurate assessment methods are needed. A number of non-invasive tests, such as embryo viability, assessment of metabolomic profile and amino acid turnover in the embryo culture media, are being evaluated in many studies and have the potential to predict which embryos have the highest implantation potential (Nagy et al 2008, Sturmey et al 2008).

The unravelling of the human genome and the increase in our knowledge of the genetic basis for many more diseases than ever imagined previously will lead to a greater understanding of the factors involved in male infertility and how to increase fecundity. This, coupled with advances in PGD, will enable accurate screening of parents for specific genes before treatment, biopsied embryos before replacement and the resulting child afterwards. Additionally, these advances will permit rapid progress in gene therapy for single or multiple gene disorders where a normal cloned gene(s) is used to replace the faulty genome.

Another challenging area for research is that of preserving fertility in children or young adults treated for cancer. As survival rates continue to improve, more young people want to know if they will be fertile, if their children will have a greater risk of developing cancer, and what alternatives exist should pelvic irradiation or chemotherapy have a permanent adverse effect on their fertility. Sperm banking is a well-recognized preservation technique for pubertal males and adults. In women, several approaches are being explored but none have been clinically established to date.

Oocyte cryopreservation is possible and requires superovulation treatment to induce multifollicular development followed by oocyte retrieval (Albani et al 2008). Oocyte cryopreservation is considered to be extremely inefficient, with approximately 100 cryopreserved oocytes needed to achieve one pregnancy. The mature oocyte is extremely fragile due to intracellular ice formation during the freezing or thawing process. There is potentially an increased risk of damage to the meiotic spindle apparatus and hardening of the zona pellucida, leading to reduced post-thaw survival, fertilization and pregnancy rates. Improvements in both

advanced vitrification and slow-freezing methods have recently resulted in an increase in the efficiency of using human cryopreserved oocytes in assisted reproduction. Although the technique is currently considered experimental, this is likely to become the fastest growing area of fertility therapy in the future. It is reassuring that no increased chromosomal abnormalities, birth defects or developmental delays have been reported in children born from cryopreserved oocytes based on the limited number of pregnancies and deliveries reported to date.

Ovarian cryopreservation has been regarded as a potential method of fertility preservation for more than a decade (Anderson et al 2008). This method has the potential advantages of preservation of a large number of oocytes within primordial follicles, it does not require hormonal stimulation when time is short, and it may be appropriate for the prepubertal. Ovarian tissues can subsequently be autotransplanted, either at orthotopic (at or around the ovarian fossa) or heterotopic locations (subcutaneously at various locations including the forearm and abdominal wall), after the patient has completed treatment. Although few livebirths following either spontaneous or IVF conceptions have been reported, more research is needed in order to enhance the revascularization process, with the goal of reducing the follicular loss that takes place after tissue grafting. These technologies are still experimental, although tremendous progress has been made recently. There are many ethical concerns with these interventions, particularly their experimental nature in emotionally vulnerable patients, who often present to ART units with unrealistic expectations, the possibility of harvesting malignant cells with germ cells, and the potential for continued transmission of germ-line mutations in cancer predisposition genes. All of these highlight the need for further research and well-designed controlled clinical trials.

The technique of in-vitro maturation (IVM) of oocytes has been practised in a few IVF units worldwide (Suikkari 2008). The primary aim of IVM is to make IVF safer and simpler for women with polycystic ovaries and those at high risk of OHSS. Immature oocytes are recovered by puncture during non-stimulated cycles or after a low-dose stimulation protocol in a woman with polycystic ovaries. Priming the follicle with FSH for 2–3 days to stimulate growth to 8–12 mm diameter has been associated with improvements in implantation rates. Additional treatment with 10,000 IU hCG 36 h before oocyte retrieval has also been shown to improve the maturation rate of immature oocytes and accelerate the maturation process. Immature oocytes collected are allowed to mature in culture for approximately 30 h before insemination or ICSI. The clinical outcome has improved substantially in recent years, with pregnancy rates of over 20% in some centres. It is estimated that over 1000 children have been born following IVM worldwide. Post-natal follow-up studies of the children have been reassuring. IVM has not yet become a mainstream fertility treatment, mainly due to its lower success rate compared with conventional IVF. Knowledge regarding the molecular mechanisms of oocyte maturation and improvement in the culture system will improve the efficacy of IVM. While there is definite benefit for the use of IVM in women with polycystic ovaries and those at risk of OHSS, its role in couples with unexplained infertility or poor ovarian reserve remains to be defined.

KEY POINTS

1. IVF/ICSI is indicated not only in cases of tubal blockage, but also for various other causes of infertility. However, it should not be used as a panacea for marital or psychosexual disorders, but to fulfil the wishes of a well-adjusted couple to have a baby.
2. Pretreatment evaluation of the couple is essential as it allows the treatment to be tailored to maximize the chances of a successful outcome following ART.
3. The aims of superovulation regimens in assisted reproduction are to maximize the number of follicles, to minimize the degree of asynchrony amongst developing follicles, and to minimize the deleterious effects of the abnormal follicular environment on luteal function and endometrial receptivity.
4. The use of GnRH agonists in stimulation protocols has increased steadily since their introduction into clinical practice, and appears to result in a reduction in cancellation rates, an increase in the number of oocytes retrieved and a significantly higher clinical pregnancy rate.
5. Whilst ovarian stimulation protocols utilizing high doses of gonadotrophins are used conventionally, a milder stimulation approach has gained a lot of interest in the IVF field recently, with the aim of minimizing the adverse effects of ovarian stimulation, particularly OHSS and multiple pregnancies.
6. Transabdominal ultrasonographic guidance to determine the precise depth of embryo placement within the uterus appears to facilitate successful ET and is therefore preferred.
7. Crude pregnancy rates per couple are almost meaningless; cumulative conception or livebirth rates should be used in reporting conventional and ART outcomes.
8. The outcome of ART depends on the age of the female partner, the duration of infertility, the multiplicity of factors responsible for the couple's subfertility, the number of embryos transferred and the number of treatment cycles that a couple undergo.
9. When four or more embryos are available for transfer, the transfer of two embryos results in equally high pregnancy and livebirth rates. However, the rate of multiple pregnancy with all its pregnancy and perinatal complications is reduced dramatically.
10. In carefully selected patients (e.g. women <37 years of age, undergoing their first IVF cycle and who have more than one top-quality embryo), eSET plus subsequent FER is as effective as double ET in terms of pregnancy rates, and significantly reduces the rate of twin pregnancies.
11. In view of the potential health risks arising from ART, it is imperative that clinicians should define the risks as those associated with the medication itself, as well as the short- and long-term physical, emotional and pregnancy-related effects.
12. The effect of ovulation induction agents currently used in ART on the risk of genital cancer risk is unclear. Considering that the treatment protocols, preparations and dosages used during IVF are relatively new, and women exposed to IVF are only beginning to reach the cancer age range, further follow-up studies are required in this area before drawing any conclusions.
13. A 30–40% increase in birth defects is reported in IVF/ICSI pregnancies compared with background risk. The increased risk of congenital malformations in ART children may largely be due to the underlying parental background, rather than the treatment techniques themselves.
14. PGD is now an established technique for the diagnosis of chromosomal or sex-linked disorders in embryos formed through ART procedures. Current evidence does not support the use of PGS to improve livebirth rates or reduce miscarriage rates in ART cycles, particularly for women of advanced age.
15. Ovarian tissue cryopreservation and oocyte cryopreservation are still considered as experimental procedures, but hold promise for future female fertility preservation.
16. IVM is a safer and simpler alternative to IVF in women with polycystic ovaries and those at high risk of OHSS.

INTRODUCTION AND DEFINITIONS	335	CONCLUSION	347
SPORADIC MISCARRIAGE	335	KEY POINTS	347
RECURRENT MISCARRIAGE	342		

Introduction and Definitions

Miscarriage is the most common complication of pregnancy and accounts for a high proportion of gynaecological consultations and hospital admissions. It can be a traumatic and highly emotional event for a woman and her partner, and the impact may be greatly underestimated by all who are involved in their care.

Current recommendations are that the term 'abortion' should be avoided in early pregnancy loss, with more sensitive terminology substituted.

- 'Spontaneous abortion' should be replaced by 'miscarriage'.
- 'Blighted ovum', 'missed abortion' or 'anembryonic pregnancy' should be replaced by 'early embryonic or fetal demise'.
- 'Incomplete abortion' should be replaced by 'incomplete miscarriage'.
- 'Recurrent or habitual abortion' should be replaced by 'recurrent miscarriage'.

At the present time in the UK, miscarriage is defined as the loss of an intrauterine pregnancy before 24 completed weeks of gestation. The World Health Organization's definition of miscarriage is the expulsion of a fetus or embryo weighing 500 g or less and also a gestational limit of less than 22 completed weeks of pregnancy.

Threatened miscarriage is defined as uterine bleeding prior to 24 weeks of pregnancy. Inevitable miscarriage can be subdivided into complete or incomplete, depending on whether or not all fetal and placental tissues have been expelled from the uterus. Early embryonic or fetal demise is where failure of the pregnancy is identified before expulsion of the fetal and placental tissues (usually by repeated ultrasound examination). Recurrent miscarriage is defined as three or more consecutive miscarriages (Stirrat 1990). This can be further subdivided into primary recurrent miscarriage, where there have been no previous live births, and secondary recurrent miscarriage, where at least one successful pregnancy has occurred previously.

In terms of investigation and further medical and surgical management, there should be a clear distinction between sporadic and recurrent miscarriage.

Sporadic Miscarriage

Epidemiology

Problems of definition and ascertainment

Problems of definition arise very early in pregnancy, where reliable detection of pregnancy is only possible with biochemical testing using urinary or serum β -human chorionic gonadotrophin (β -hCG), and also in late pregnancy, where the distinction between a late mid-trimester miscarriage and a stillbirth can be difficult (Chard 1991). The ideal research model for determining rates of miscarriage is a prospective longitudinal study of a representative cross-section of the population which is capable of recognizing all conceptions immediately, takes account of termination of pregnancy and follows women through the first 20 weeks of pregnancy (Regan et al 1989, Alberman 1992).

Early histological work from the 1950s (Hertig et al 1959), in which fertilized ova were directly observed in 107 hysterectomy specimens from women who had intercourse around the time of expected ovulation prior to their operation, suggests a postimplantation pregnancy rate of 58% (21 of 36 possible conceptions). In a mathematical model, total pregnancy loss rates have been estimated at 78% (Roberts and Lowe 1975).

Rate of miscarriage

Following critical review of the literature, a reasonably coherent picture is emerging (Figure 23.1). Estimates of early reproductive loss rates in the peri-implantation period of approximately 50–70% still rest largely on the early work of Hertig, although data derived from in-vitro fertilization (IVF) studies support losses of this order of magnitude (Chard 1991).

Postimplantation and biochemical pregnancy loss rates appear to be of the order of 30%, whereas recognized pregnancy losses after clinical recognition of pregnancy remain consistent in most studies as 10–15% (Table 23.1).

Aetiology

Chromosomal abnormalities

Miscarriage is a heterogeneous condition, but the single largest cause of sporadic miscarriage is fetal chromosomal abnormalities, accounting for approximately 50% of all cases (Table 23.2).

It is difficult to establish the precise contribution made by fetal chromosomal abnormalities. The figures in Table 23.2 are probably an underestimate, since miscarriages occurring as a result of fetal chromosomal anomalies are maximal at the earliest and least well-documented stages of pregnancy. Evidence from preimplantation genetic diagnosis studies of embryos created as a result of IVF suggests that at least 65% of all embryos are chromosomally abnormal (Gianaroli et al 2000). However, extrapolation of these results to miscarriage in the general population must be cautious, given the high degree of selectivity of these patients and a different micro-environment at fertilization.

Trisomies are the major fetal chromosomal abnormality in sporadic cases of miscarriage, being found in 30% of all miscarriages and 60% of chromosomally abnormal miscarriages. Trisomies, together with monosomy X (15–25%) and triploidy (12–20%), account for over 90% of all chromosomal abnormalities found in sporadic cases of miscarriage.

Trisomies for all chromosomes have been described, with the exception of chromosomes 1 and Y, although the relative frequencies are vastly different. Chromosome 16 and, to a lesser extent, chromosomes 2, 13, 15, 18, 21 and 22, account for the majority of trisomic abnormalities (Figure 23.2). Most trisomies are believed to be a consequence of non-disjunction during maternal meiosis. Trisomy 16 gives rise to only the most rudimentary embryonic growth with an empty sac (Edmonds 1992), and other trisomies often result in early embryonic demise.

Monosomy X (45XO) is thought to result from paternal sex chromosome loss (which can be either X or Y). It is usually associated with the presence of a fetus, although focal abnormalities, such as encephalocele or hygromata, may occur (Edmonds 1992).

Figure 23.2 Distribution of differing trisomies in sporadic cases of miscarriage.

Polyploidy results from the addition of complete haploid sets of chromosomes. Most common are triploid miscarriages, usually 69XXY or 69XXX, which are thought to result from dispermic fertilization. These pregnancies are also characterized by multiple fetal and placental changes, such as neural tube defects, omphalocele, hydropic villi and intrachorial haemorrhage. Tetraploid pregnancies are rare and usually do not progress beyond the third week of embryonic life.

Structural chromosome abnormalities have been reported, although minor abnormalities are no less frequent in live births compared with miscarriages. Major structural defects may arise *de novo* or be inherited. They are rarely a cause of sporadic miscarriage but are associated with recurrent miscarriage.

There appears to be a difference in the gestational age of pregnancy loss between different types of chromosomal abnormality, with trisomic and monosomic pregnancies miscarrying at a modal peak of 9 weeks and triploid pregnancy losses spanning 5–16 weeks of gestation (Alberman 1992).

Fetal malformations other than those caused by chromosomal anomaly

There is little doubt that the risk of miscarriage is increased with fetal malformation (Alberman 1992). However, since there has been no systematic search for malformations in fetal loss and since, in some cases, the malformation is secondary to a chromosomal anomaly, it is very difficult to assess the size of the increased risk. A single published study (Shephard et al 1989) has demonstrated an increased neural tube defect rate (3.6%) and an increased facial cleft rate (2.7%) amongst spontaneous miscarriages. Overall, the proportion of miscarriages as a result of fetal abnormalities without any associated chromosomal anomaly is small.

Placental abnormalities

Histological analysis of placental tissue from sporadic miscarriages has revealed several different patterns (Rushton 1995). These either point towards early fetal or embryonic demise with essentially normal placentation, or they have

shown abnormal placental villous development with marked villous hypoplasia, reduced vascularization, enlarged intra-villous spaces, often with clots and lacking significant extravillous trophoblastic infiltration, or with acute necrotic changes in the villi and associated clots which can be either patchy or global. Other reported placental changes have included inflammatory changes or a mixture of the above changes.

Amongst sporadic miscarriages, abnormalities of villous development have been reported fairly consistently at 30–40% (Hustin and Jauniaux 1997). However, the causes leading to the majority of these cases of abnormal placentation and therefore subsequent miscarriage remain unknown. Although autoimmune and infective causes can be associated with abnormal villous development, most inherently abnormal embryos probably also have abnormal placentation.

At present, although routine histological analysis of all products of conception is indicated in order to exclude molar and ectopic pregnancies, it is of little benefit in determining the cause of sporadic miscarriage.

Infection

Infection has been cited as a cause of late pregnancy loss and also early pregnancy loss for the past century. However, the precise role of infection as a cause of sporadic miscarriage is poorly and inconsistently reported (Simpson et al 1996). In many cases, whether infection has actually preceded any fetal demise or merely arose afterwards remains satisfactorily unanswered.

Several organisms have been associated with miscarriage (Box 23.1). *Listeria*, toxoplasmosis, herpes varicella zoster and malaria (*Plasmodium falciparum*) appear to be the most clinically important pathogens in women with early miscarriage.

Rubella infection, although a cause of first-trimester miscarriage, is now rare. The role of cytomegalovirus is unclear, although primary infection may cause miscarriage. The role of chlamydia infection, whether via an acute primary infection or a resultant chronic endometritis, also remains unclear. An association between herpes simplex virus infection and early pregnancy loss was first reported in the 1970s

(Nahmias et al 1971), although later prospective studies have failed to show any association with sporadic or recurrent miscarriage even when primary infection occurred in the first trimester (Stray-Pedersen 1993). It remains unknown whether human immunodeficiency virus (HIV) is an important cause of early pregnancy loss. Some studies have demonstrated an increased rate of early pregnancy loss with HIV (d'Ubaldo et al 1998), while others have not (Bakas et al 1996). Whether any increased risk of miscarriage is the result of the virus, the mother's general health or her immunocompromised status remains unclear.

Syphilis (*Treponema pallidum*) and parvovirus B19 are more commonly a cause of late second-trimester miscarriage and stillbirth, whilst group B streptococcus has been implicated in late miscarriage and preterm labour. Bacterial vaginosis (*Trichomonas vaginalis*) is also associated with late second-trimester miscarriage and preterm labour, but the use of metronidazole or other antibiotics in women with demonstrable bacterial vaginosis infection does not reduce late miscarriage or preterm delivery rates (Carey et al 2000).

Fetal sex, multiple pregnancy, maternal age and parity

Most studies have reported an excess of males in miscarriages and pregnancies complicated by varying degrees of placental dysfunction (Kellokumpu-Lethinen and Pelliniemi 1984, Edwards et al 2000). However, the sex ratio of most early conceptions still remains unknown.

Multiple pregnancy is associated with an increased risk of fetal loss, either via early resorption, postimplantation loss or second-trimester miscarriage. In early pregnancy, the risk of miscarriage is twice that of singleton pregnancies (Sebire et al 1997a). The rate of late pregnancy loss is also increased, particularly in monochorionic twin pregnancies,

Figure 23.3 The risk of miscarriage in first pregnancies with maternal age.

Adapted from Alberman E 1992 Spontaneous abortions: epidemiology. In: Stabile I, Grudzinskas G, Chard T (eds) Spontaneous abortion — diagnosis and treatment. Springer-Verlag, London.

where late miscarriage rates can approach 12% (Sebire et al 1997b).

The risk of miscarriage rises with parity; however, the rise is a result of reproductive compensation (Alberman 1987). The risk of miscarriage in first pregnancies is low in young women (Regan et al 1989), but rises significantly after the age of 39 years (Figure 23.3). This rise is not only found in association with trisomic pregnancies (which rise with maternal age) but also in chromosomally normal pregnancies.

Maternal health

Virtually every maternal medical disorder has been associated with sporadic miscarriage. Women with severe medical disease rarely become pregnant, but if they do, their disease may deteriorate during pregnancy. Various mechanisms, including endocrinological, immunological or infective, have been suggested. Poorly controlled diabetes is associated with an increased risk of miscarriage (Mills et al 1988), whereas well-controlled and subclinical diabetes can rarely be considered a cause. Overall, only a small fraction of all early pregnancy losses can be considered to be attributable to severe maternal disease.

Cigarette smoking has been positively correlated with miscarriage, and a review of the effects of nicotine on ovarian, uterine and placental function suggests that cigarette smoking has an adverse effect on trophoblast invasion (Schiverick and Salafia 1999). Cocaine use has also been reported to increase the risk of miscarriage (Ness et al 1999). Alcohol consumption has been shown to be higher in women whose pregnancies ended in miscarriage compared with pregnancies which proceeded beyond 28 weeks of gestation (Harlap and Shapiro 1980, Kline et al 1980), although other studies have not confirmed this observation (Halmesmaki et al 1989, Parazzini et al 1990). There is some evidence to suggest that even moderate maternal alcohol consumption is associated with an increased risk of miscarriage (Windham et al 1997). Many studies have shown a relationship between coffee/caffeine intake and spontaneous miscarriage, although these have not controlled for other confounding variables. Only high levels of caffeine metabolites in maternal serum

are associated with miscarriage, so it would appear that moderate consumption of caffeine is unlikely to increase the risk of miscarriage (Klebanoff et al 1999).

Some chemical agents including lead, ethylene oxide, solvents, pesticides, vinyl chloride and anaesthetic gases have been shown to have some association with fetal loss (Cohen et al 1971, Mur et al 1992, Rowland et al 1996, McDonald et al 1988). Although many environmental toxicologists accept these agents as proven, the evidence for low levels of exposure remains far from convincing.

Radiotherapy and chemotherapeutic agents are accepted causes of miscarriage (Zemlickis et al 1992), although they are only administered during pregnancy in seriously ill women. Although significant ionizing radiation for diagnostic purposes can lead to fetal malformation and miscarriage, a dose of more than 25 rads is associated with a 0.1% risk of abnormality (1 rad is the equivalent of eight to 10 abdominal/pelvic X-ray films).

There is a small increase in the risk of spontaneous miscarriage with general anaesthesia and incidental surgery during the first and second trimesters, although this is higher with gynaecological surgery (Duncan et al 1986).

It has been claimed that impaired psychological well-being predisposes to fetal loss (Stray-Pedersen and Stray-Pedersen 1984), although it has been difficult to exclude other confounding variables. Despite problems with recall bias, there are an increased number of negative life events in women with chromosomally normal as compared with chromosomally abnormal miscarriages (Neugebauer et al 1996), but no differences in hormonal markers of stress have been determined.

Pathophysiology

The exact pathophysiology resulting in the uterine expulsion of early pregnancy remains unknown. Abnormal placentation (either primary or itself secondary to early fetal demise) can either lead to reduced or shallow uterine invasion by the trophoblast, or can itself be caused by reduced invasion. In this situation, the usual reduction in maternal vascular tone cannot occur. It is presumed that this blood flow enters the intervillous space and dislodges the conceptus, thereby leading to embryonic demise if this has not already occurred (Rushton 1995). Nevertheless, even quite large intrauterine haematoma visualized by ultrasound have not prevented live births at term (Pedersen and Mantoni 1990), and the presence of haematoma *per se* does not increase the risk of miscarriage (Tower and Regan 2001).

Once the conceptus is dislodged, there is further intrauterine bleeding. Local prostaglandin release will lead to pain and ultimately expulsion of the conceptus and any associated blood.

Presentation

Threatened miscarriage

This can be defined as uterine bleeding before 24 weeks of pregnancy (the time of presumed fetal viability) with no evidence of any fetal or embryonic demise. It is usually painless. Characteristically, the bleeding is initially bright red, followed by a reducing brown loss. This can affect up to 25% of all pregnancies and is one of the most common indica-

Figure 23.4 Ultrasound picture of an ongoing pregnancy with an intrauterine haematoma in a woman who presented with a threatened miscarriage.

tions for emergency early pregnancy referral. Clinical examination reveals a soft, non-tender uterus, usually of the appropriate gestational size, and a closed cervix. Transvaginal or transabdominal ultrasound scan confirms an ongoing pregnancy (Figure 23.4).

The non-specific nature of abdominal pain, vaginal bleeding and pelvic tenderness precludes their use as predictors of ultimate outcome in women with threatened miscarriage. However, continued vomiting (rather than nausea alone) in early pregnancy is associated with an increased chance of live birth (Weigel and Weigel 1989), presumably because it indicates continued placental hormone production.

Inevitable miscarriage

Miscarriage is a process rather than a single event. Of all women presenting with bleeding in early pregnancy, approximately 50% will ultimately miscarry (Stabile et al 1987). Whilst the cervix remains closed, any pain and bleeding may subside and the pregnancy may continue otherwise normally to term. However, once the cervix opens, miscarriage is inevitable.

Usually, women present with crampy abdominal pains and fresh bleeding. Symptoms alone are unreliable and the diagnosis is determined by the confirmation of cervical dilatation at vaginal examination. Examination often reveals a tender, firm uterus, which may be smaller than the expected gestational size, and the cervical os is open. Products of conception may also be felt through the os.

Occasionally, the woman may present with severe shock. This can either be secondary to massive haemorrhage, which will require appropriate emergency resuscitation, blood transfusion and uterine evacuation, or the degree of shock may be out of proportion to the blood loss and is due to the distension of the cervix by products of conception and the resultant sympathetic stimulation. This is termed 'cervical shock syndrome' and is often severe. Quick removal of the products from the os, at the bedside, results in relief of the shock. In rare cases, endotoxic shock secondary to sepsis may occur.

Complete and incomplete miscarriage

Inevitable miscarriage is either complete or incomplete depending on whether or not all fetal and placental tissues have been expelled from the uterus. The typical features of incomplete miscarriage are heavy bleeding (which may be intermittent) and abdominal cramps. The finding of a dilated cervix on examination in the presence of continued pain and bleeding is usually diagnostic. Ultrasound scan will confirm the presence of retained products of conception (Figure 23.5).

If the symptoms of incomplete miscarriage resolve spontaneously, complete miscarriage may have occurred. Nevertheless, following abdominal and pelvic examination, ultrasound may need to be performed to confirm that the uterus is indeed empty. Occasionally, the cervix may close despite the presence of retained products. The number of complete miscarriages is unknown. Many such early miscarriages may go unreported. Early studies of women with threatened miscarriage showed complete miscarriage rates of less than 1% (Stabile et al 1987), although more recent evidence suggests that approximately 20–30% of miscarriages are complete (Chung et al 1994, Mansur 1992). Similarly, expectant management of early fetal demise has demonstrated that, with time, up to 25% of women go on to have a complete miscarriage (Jurkovic et al 1998).

Early fetal demise (missed abortion/miscarriage)

'Early embryonic or fetal demise' is now the preferred term in both the UK and the USA, rather than 'missed abortion' or 'missed miscarriage'. Previously, this has also been termed an 'anembryonic pregnancy' (all pregnancies develop from an embryo) or 'blighted ovum' (the pregnancy cannot result from an ovum alone). These terms should also be abandoned.

Early fetal demise is where failure of pregnancy is identified before any expulsion of the products of conception occurs. The woman may report a disappearance of the symptoms and signs of early pregnancy, such as nausea and vomiting or breast tenderness. A brown vaginal loss may also be reported. The diagnosis may also be made in otherwise

asymptomatic women at routine obstetric/dating ultrasound examination. The diagnosis is made by the lack of fetal heart activity in a pregnancy with a crown–rump length of over 5 mm (Pennell et al 1991), or when two ultrasound examinations 1 or 2 weeks apart have shown no growth and no fetal heart activity. In cases of doubt, a repeat ultrasound is always indicated. Occasionally, a collapsing gestational sac or a failed pregnancy surrounded by clot *in utero* may be seen (Figure 23.6). Abdominal and pelvic examination often reveals a uterus smaller than expected for the gestational age and a closed cervical os.

Sepsis

This occurs when infection complicates miscarriage or termination of pregnancy. Intrauterine sepsis rarely follows incomplete miscarriage, although the incidence is considerably higher at approximately 3.6% following termination of pregnancy (Frank 1985). The most common infecting organisms are *Escherichia coli*, *Bacteroides*, streptococci (both anaerobic and occasionally aerobic) and *Clostridium welchii*. Occasionally, a history of intrauterine instrumentation may be withheld. The woman usually presents with suprapubic pain, malaise, fever and, occasionally, vaginal bleeding. Findings on examination include abdominal rigidity, uterine and adnexal tenderness, and a closed cervical os. Rarely, septicaemia may ensue, leading to bacteraemic endotoxic shock and possibly maternal death.

Trophoblastic tumours

Trophoblastic tumours include complete and partial hydatidiform moles, choriocarcinoma and placental site tumours. These occasionally present as threatened miscarriage, and suggestive features are noted at ultrasound examination. Trophoblastic tumours are discussed in Chapter 43.

Investigations

Ultrasound, usually transvaginal, is essential in the diagnosis of miscarriage. It will determine the presence of an ongoing pregnancy in cases of threatened miscarriage, and distinguish between early fetal demise, incomplete miscarriage

Figure 23.5 Ultrasound picture of incomplete miscarriage demonstrating retained products of conception within the endometrial cavity.

Figure 23.6 Ultrasound picture of early fetal demise, showing a collapsing gestation sac.

and complete miscarriage in failing pregnancies. Ultrasound is also important in the diagnoses of ectopic pregnancy and trophoblastic disease.

Reliable pregnancy testing, whether by urinary or serum β -hCG, is also essential in order to distinguish an early complete miscarriage or an ongoing ectopic pregnancy.

All women with uterine bleeding in early pregnancy should have their blood group determined, and all women who are Rhesus (D) negative should receive anti-D immunoglobulins regardless of the gestational age of the pregnancy.

The measurement of other fetoplacental hormones and proteins, such as α -fetoprotein, Schwangerschaft protein 1, human placental lactogen, pregnancy-associated plasma protein, oestrogen and progesterone, have all been reported as diagnostic tests in early pregnancy. In rare cases, they may improve the prediction of both early fetal demise and ectopic pregnancy (Grudzinskas and Chard 1992), but their routine use is not indicated.

Treatment

Threatened miscarriage

Early studies demonstrated that the presence of fetal heart activity at ultrasound examination in women who present with a history of bleeding in early pregnancy was associated with a high chance (97–98%) of a live birth (Stabile et al 1987). More recent evidence confirms livebirth rates of 90–95% for younger women, but for women over 40 years of age, miscarriage rates of 15–30% are reported even after the identification of fetal heart activity (Deaton et al 1997, Schmidt-Sarosi et al 1998). Nevertheless, for most women, reassurance and continued medical and emotional support are all that is required.

Bed rest and avoiding penetrative intercourse have historically been advised. If the vascular hypothesis for the pathophysiology of miscarriage is accepted (Hustin and Jauniaux 1997), bed rest may improve pressure variation and flow changes, and therefore improve the outcome. However, there is a paucity of clinical evidence to support this hypothesis. Initial presentation is usually in primary care and, currently, over 96% of general practitioners still advise bed rest and the avoidance of intercourse, although many believe that it does not improve the eventual outcome.

Progesterone supplementation in early pregnancy has been prescribed for over 30 years for women presenting with threatened (and also recurrent) miscarriage. The historical rationale was that a progesterone deficiency would lead to miscarriage. Obviously, the converse may also be true; a failed pregnancy may lead to a progesterone deficiency. There is a wealth of published data, mostly from uncontrolled treatment trials. However, several meta-analyses (Daya 1989, Goldstein et al 1989) have been unable to demonstrate a beneficial effect for progesterone treatment. The routine use of progesterone in threatened miscarriage cannot be justified.

Incomplete miscarriage

Surgical evacuation of the uterus after cervical dilatation, if necessary, has remained the cornerstone of management of incomplete miscarriage in the industrialized world since the

1940s (Hertig and Livingstone 1944). Evacuation and curettage have been regarded as essential to ensure that the uterine cavity is empty, otherwise haemorrhage, infection and later complications such as Asherman's syndrome may result. Early studies showed a maternal mortality rate of 1.6% in women who did not undergo surgical treatment (Russell 1947). In cases of haemodynamic compromise of cervical shock, appropriate resuscitation and urgent surgical evacuation are indicated. Most cases are performed under general anaesthesia, although effective outpatient curettage has been reported (Fawcus et al 1997). Suction evacuation is generally regarded as a safer technique than sharp curettage, with lower rates of perforation, blood loss and subsequent intra-uterine adhesion formation (Edmonds 1992, Verkuyl and Crowther 1993).

The routine use of syntocinon or ergometrine has shown no benefit in reducing blood loss during the surgical treatment of first-trimester incomplete miscarriage (Beeby and Morgan Hughes 1984). Due to the risk of ascending infection and its sequelae, whenever uterine instrumentation is performed, screening for chlamydia infection is recommended, although the use of prophylactic doxycycline is only likely to be of benefit in areas of relatively high prevalence (Prieto et al 1995).

Although a minor procedure, surgical evacuation is associated with rare but serious morbidity. Complications include tearing or lacerations to the cervix, perforation of the uterus, which may also lead to bowel perforation, bladder perforation, damage to the broad ligament, infection, Asherman's syndrome (intrauterine adhesions) and haemorrhage (Ratnam and Prasad 1990). The incidence of serious morbidity has been estimated at 2.1% (Lawson et al 1994, Royal College of General Practitioners/Royal College of Obstetricians and Gynaecologists 1985), of which the most common problem is infection. This can lead to later sequelae including secondary infertility, ectopic pregnancy and Asherman's syndrome. The incidence of mortality associated with surgical evacuation of the uterus has been estimated at 0.5 per 100,000 (Lawson et al 1994).

Recent studies demonstrated the efficacy of expectant management or 'observation alone' in women with incomplete miscarriage (Nielsen and Hahlin 1995, Hurd et al 1997). In cases where there was no haemodynamic compromise or maternal anaemia, spontaneous resolution occurred within 3 days in up to 80% of cases with minimal retained products (15–50 ml). Therefore, in women with minimal intrauterine tissue (after ectopic pregnancy has been excluded), expectant management is safe. However, large volumes of retained products are associated with an increase in complications, primarily infection and prolonged bleeding (Hurd et al 1997). There is no evidence that future fertility is impaired following expectant management (Kaplan et al 1996).

Herbal remedies have been used in the past to encourage the uterus to expel its contents, but an effective non-surgical alternative to termination of pregnancy and miscarriage had to await the development of the antiprogesterone mifepristone and the prostaglandin analogues gemeprost and misoprostol. Their efficacy has been demonstrated in the treatment of incomplete miscarriage (Henshaw et al 1993, Ashok et al 1998), leading to complete miscarriage rates of approximately 95%.

The use of medical treatment or the adoption of an expectant approach in appropriately selected cases may have many medical and economic benefits. However, many women continue to express a preference for surgical treatment (Hamilton-Fairley and Donaghy 1997), citing fears regarding pain, bleeding and the length of time to resolution in the non-surgical group.

Early fetal demise

The treatment options for early fetal demise are essentially the same as for incomplete miscarriage. Surgical treatment should be preceded by cervical ripening agents (mifepristone or prostaglandins) in order to reduce the risks of cervical trauma or uterine perforation associated with forced cervical dilatation. Gemeprost, mifepristone, and oral or vaginal misoprostol seem to be equally effective (Gupta and Johnson 1992, Platz-Christiansen et al 1995, Ayres de Campos et al 2000). Expectant management is feasible, although less effective than in cases of incomplete miscarriage, with only 25% proceeding to complete miscarriage (Jurkovic et al 1998). The efficacy of medical treatment is also less when compared with incomplete miscarriage, although complete miscarriage rates of up to 90% have been reported with higher doses of mifepristone and misoprostol and a longer surveillance period (El-Refaey et al 1992).

Psychological aspects

Psychological consequences of early pregnancy loss differ widely among different women, different families and even different pregnancies in the same woman. Nevertheless, most women, irrespective of their attitude towards the pregnancy at the time, experience feelings of depression and anxiety following miscarriage (Seibel and Graves 1980), and up to 36% of women are 'highly symptomatic' in terms of clinical depression 4 weeks after miscarriage (Neugebauer et al 1992).

All workers caring for women with miscarriage and their families need to understand the increased psychiatric morbidity associated with pregnancy loss, and be able to offer appropriate support both at the time of diagnosis and also after treatment. Good communication with providers of primary care for the whole family and access to counselling are important, since 'miscarriages do not occur in a uterus but in a woman, and miscarriages do not occur solely in a woman but in a family' (Cain et al 1964). For some couples, the use of ritual can help them through the bereavement process (Hopper 1997).

In subsequent pregnancies, many women will need considerable reassurance and support (Hamilton 1989), and early access to ultrasound and hospital services may be required.

Recurrent Miscarriage

In contrast to sporadic miscarriage, recurrent miscarriage is relatively uncommon. A history of three or more consecutive miscarriages occurs in 0.5–2% of women (Stirrat 1990, Daya 1993, Katz and Kuller 1994). Recurrent miscarriage is obviously distressing and frustrating for both the couple concerned and those treating them. In many cases, the cause may not be apparent despite intensive and expensive clinical

and laboratory testing, and there remains only a limited understanding of the causes of recurrent miscarriage.

The aetiologies are outlined below and summarized in Box 23.2. The management of recurrent miscarriage, including unexplained recurrent miscarriage, will be discussed below under specific headings. Unexplained miscarriage occurs in approximately 50% of women attending specialist recurrent miscarriage clinics (Clifford et al 1994, Stephenson 1996, Li 1998).

Genetic factors

Parental chromosomal abnormalities

Parental chromosomal abnormalities are the most important genetic anomalies currently detectable amongst couples with recurrent miscarriage. Most studies report an incidence of 3–5% (Stray-Pedersen and Stray-Pedersen 1984, Clifford et al 1994, Stephenson 1996, Li 1998), compared with an incidence of 0.5% in the general population.

Balanced or reciprocal translocations are the most frequently detected parental chromosomal anomaly in couples with recurrent miscarriage. The male:female ratio is approximately 1:2. A portion of one chromosome is exchanged with a portion of another, resulting in two abnormal chromosomes but, overall, a normal chromosomal complement. Translocations have been reported for all chromosomes in many different combinations. At gametogenesis, there is a 50% chance of a chromosomally abnormal gamete being produced. However, there appears to be a lower fertilization or implantation rate with abnormal gametes, since chorionic villus sampling and amniocentesis have demonstrated a 40% and 11% risk, respectively, of a chromosomally unbalanced fetus (Mikkelsen 1985).

Robertsonian translocations are less common, occurring in approximately 1% of couples with recurrent miscarriage.

Box 23.2 Summary of the potential causes of recurrent miscarriage

Genetic

- Parental chromosomal abnormalities
- Recurrent aneuploidy
- Other genetic causes

Anatomical

- Uterine anomalies
- Cervical incompetence

Infective

- Predisposition to infection
- Possible pathogens

Endocrine

- Luteal-phase deficiency
- Thyroid disease
- Hypersecretion of LH/polycystic ovary syndrome

Immunological

- Antiphospholipid syndrome
- Other thrombophilic defects
- Alloimmune

Here, two chromosomes adhere to each other at either the centromere or the short arms of the chromosome. This leads to a total chromosome count of 45 but a normal chromosome complement overall. The risks of recurrence and miscarriage vary in different Robertsonian translocations. The most common translocation (involving chromosomes 14 and 21) results in 10–15% of pregnancies with trisomy 21 (Boué and Gallano 1984). If homologous chromosomes are involved, the risk of a chromosomally abnormal conceptus is 100%.

Pericentric chromosomal inversions occur in approximately 1% of the general population, and are not considered to be of clinical significance for recurrent miscarriage.

Peripheral blood karyotyping should be performed in both partners of all couples with recurrent miscarriage to determine any parental chromosome abnormality. Specialized genetic counselling is essential and offers the couple a prognosis for future pregnancies; this may, in some cases, not be as bleak as anticipated. There should also be the opportunity to discuss preimplantation genetic diagnosis and antenatal fetal karyotyping, including chorionic villus sampling and amniocentesis. In cases of homologous Robertsonian translocations, gamete donation and/or effective contraception should be discussed.

It is important to note that over 35% of couples with a significant parental chromosomal abnormality have already achieved a successful pregnancy in addition to their miscarriages (Clifford et al 1994).

Recurrent aneuploidy

Some couples have an increased risk of miscarriage because they produce recurrent aneuploid fetuses. This may be the result of an increased tendency to non-disjunction, either inherited or induced environmentally. Chromosomal abnormalities are seen with a higher frequency amongst preimplantation embryos created during IVF from couples with a history of recurrent miscarriage (Vidal et al 2000). Presumably, these are the result of errors in gametogenesis, and much current research is focused on the role of sperm chromosome abnormalities in recurrent miscarriage.

Other genetic factors

The karyotype of many recurrent miscarriage conceptions may be euploid (46XX or 46XY), and in the absence of any other identifiable cause or association, these unexplained recurrent early pregnancy losses may be the result of molecular mutations or single gene defects. Chromosome analysis itself is a very crude tool to determine genetic abnormalities. So far, there has only been one report of a specific single gene locus abnormality associated with recurrent miscarriage (Pegoraro et al 1997), but much work remains to be done. The impact of other genetic factors on recurrent miscarriage is confirmed by the increased incidence amongst consanguineous couples (Hendrick 1988).

Anatomical factors

Uterine anomalies

The reported incidence of uterine anomalies in women with recurrent miscarriage varies widely from as low as 1% up to 27% (Regan 1997). Described anomalies vary from uterus

didelphus to subseptate uteri, and some studies even include submucosal fibroids. The incidence of such anomalies in the fertile population has been reported to be 1.8–3.6% (Ashton et al 1988).

The significance of such anomalies, particularly intrauterine septae, arcuate uterus and submucosal fibroids, in women with recurrent miscarriage is unclear. Historically, uterine anomalies were associated with second-trimester miscarriages, but later reports have also shown an increase in early miscarriages. The exact aetiology is unknown, although implantation over a septum or similar defect may result in decreased vascularity of the placenta.

Hysterosalpingography (HSG), laparoscopy and hysteroscopy, magnetic resonance imaging, computed tomography and three-dimensional ultrasound have all been used in the diagnosis and evaluation of uterine anomalies. Although HSG has traditionally been used as the primary screening test, three-dimensional ultrasound shows promise as a less invasive screening tool (Jurkovic et al 1995). In most cases, further evaluation at laparoscopy and hysteroscopy is indicated (Figure 23.7).

Figure 23.7 (A) Hysterosalpingogram demonstrating a septate uterus. (B) Three-dimensional ultrasound demonstrating a septate uterus.

Treatment of uterine anomalies in women with recurrent miscarriage remains controversial. Many reports demonstrate a benefit of hysteroscopic or conventional metroplasty in women with septate, subseptate or bicornuate uterus who have suffered mid-trimester miscarriage compared with matched controls (Candiani et al 1990, Ayhan et al 1992, Pabuccu et al 1995, Heinonen 1997). However, the likelihood of a live birth in untreated women is as high as 66% (Heinonen 1997), and a similar percentage of women presenting with recurrent miscarriage have already achieved a live birth (Clifford et al 1994). Open pelvic surgery, in particular, has been associated with subsequent infertility (Bennett 1987). The value of corrective uterine surgery in women with these anomalies and a history of early pregnancy loss is uncertain (Ben-Rafael et al 1991). Similarly, the value of transcervical myomectomy in women with submucous fibroids remains unknown, although there have been initial successful reports (Egwuatu 1989).

Cervical incompetence

Cervical incompetence is usually associated with miscarriage occurring after 12–14 weeks or premature labour. It usually presents as silent dilatation of the cervix without painful contractions. The membranes bulge through the cervical canal and eventually rupture spontaneously.

The diagnosis of cervical incompetence poses a difficult problem (Medical Research Council/Royal College of Obstetricians and Gynaecologists Working Party on Cervical Cerclage 1993). It is usually based on a previous history of mid-trimester miscarriage in the absence of painful uterine contractions. Vaginal ultrasound may be useful to detect early features of cervical incompetence (shortening or funnelling) (Althuisius et al 2000), but neither ultrasound nor HSG has been found to be useful in the diagnosis of cervical incompetence before pregnancy.

Treatment of cervical incompetence is cervical cerclage in pregnancy, usually after 12–14 weeks when the toll of first-trimester miscarriages has occurred and after screening for chromosomal abnormalities has been performed. It has traditionally involved the insertion of a MacDonald suture, where a tape is inserted round the exposed vaginal cervix (MacDonald 1957), or a Shirodkar suture, where the vaginal mucosa is incised and the bladder reflected, allowing insertion of the suture at a higher level of the cervical canal (Shirodkar 1960). Modifications of this procedure have included burying the suture under the vaginal mucosa at the end of the procedure. In the authors' experience, this is rarely accompanied by significant vaginal discharge. The MacDonald suture is more widely used and less traumatic to the cervix than the Shirodkar suture, although the exposed tape remains a possible focus for later infection. More recently, emergency cervical cerclage in women who present acutely in the mid-trimester with silent cervical dilatation and/or herniation of the membranes through the cervix has been reported with livebirth rates of 50–60% (Wong et al 1993, Aarts et al 1995). Nevertheless, there are high rates of premature delivery and infection, including chorioamnionitis, in over 30% of cases.

In some women, particularly where the diagnosis is unsure or in those who have other risk factors, regular ultrasound monitoring of the cervix can be performed. If there is

funnelling or shortening of the cervix, emergency cerclage can be performed (Althuisius et al 2000). Ultrasound may also be useful in women who have already had cervical cerclage in order to warn of problems (Dijkstra et al 2000). Transabdominal cervical cerclage may be useful in a highly selected group of women with anatomical defects in the cervix and previous mid-trimester miscarriages or preterm labours following failed vaginal cervical cerclage (Gibb and Salaria 1995). Laparoscopic transabdominal cervical cerclage has also been reported (Scibetta et al 1998), but neither of these procedures have been assessed in appropriate trials.

Infective factors

Although any severe infection may lead to sporadic miscarriage, for infection to be a cause of repeated pregnancy failure it must persist in the genital tract and usually be asymptomatic.

Syphilis (*Treponema pallidum*) is a cause of recurrent late second-trimester miscarriage and stillbirth. Screening is performed routinely, and treatment with penicillins is effective. It is a rare cause of recurrent miscarriage in developed countries. Malaria infection in non-immune women is also associated with recurrent miscarriage in endemic areas (Royal College of Obstetricians and Gynaecologists 2001).

Bacterial vaginosis (*Trichomonas vaginalis*) is associated with recurrent late second-trimester miscarriage and preterm labour (Hay et al 1994), although there is no association with early pregnancy loss (Llahi-Camp et al 1996). Treatment with metronidazole has not been shown to be effective (Carey et al 2000).

The identification of individual organisms has proven to be disappointing in the search for causes of early or late recurrent miscarriage, which suggests that pregnancy outcome may be determined by maternal or fetal response to infection rather than the infective organism itself. Gene mutations, such as those associated with mannose-binding protein (MBP) deficiency, are an important cause of inherited immunodeficiency and increased susceptibility to infection. Early studies demonstrate a trend in association between late miscarriage and MBP genes (Baxter et al 2001). Future research regarding the role of infection in recurrent miscarriage needs to explore genetic susceptibility.

In women with a history of recurrent mid-trimester miscarriage, regular gentle sterile speculum examination to assess any cervical change, and regular high and low vaginal swabs to screen for any infection can be performed. This approach is empirical but it is difficult not to treat women with demonstrable infection. Similarly, low-dose maintenance antibiotic therapy may be used in women with repeated positive results, although this is also empirical.

Endocrine factors

Systemic endocrine disease

As discussed previously, diabetic women with good metabolic control are no more likely to miscarry than non-diabetic women. However, diabetic women with high glycosylated haemoglobin A_{1c} levels in the first trimester are at significantly higher risk of both miscarriage and fetal mal-

formation (Hanson et al 1990). As the risk of miscarriage is only increased in women with poorly controlled diabetes mellitus, there is no value in screening for occult disease in asymptomatic women.

Although thyroid autoantibodies are associated with an increased risk of miscarriage, this is secondary to a generalized autoimmune abnormality rather than a specific thyroid dysfunction (Singh et al 1995). Screening asymptomatic women with a thyroid function test is unhelpful as they are usually normal (Clifford et al 1994, Rushworth et al 2000).

Luteal-phase deficiency

A functional corpus luteum is essential for the implantation and maintenance of early pregnancy, primarily through the production of progesterone, which is responsible for the conversion of a proliferative endometrium into a secretory endometrium available for embryo implantation. Disorders or removal of the corpus luteum can result in infertility and early pregnancy loss (Miller et al 1969, Csapo et al 1973). Although much controversy exists about luteal function, the success of oocyte donation with oestradiol and progesterone support in the absence of any ovarian activity would suggest that its effects are primarily progesterone determined.

The prevalence of a luteal-phase defect is reported to occur in 23–60% of women with recurrent miscarriage (Li and Cooke 1991), although it is difficult to determine the exact proportion of women with luteal-phase problems because of difficulties in diagnosis. The diagnosis is usually determined by low luteal-phase progesterone level and/or a non-secretory endometrium, by biopsy, in non-fertile, non-pregnant cycles (Jordan et al 1994, Serle et al 1994). Between 30% and 50% of cases of luteal-phase defect, as determined by endometrial histology, are found in the presence of normal circulating progesterone levels, suggesting that a primary endometrial defect is as common as deficient progesterone production (Li et al 1991). There is no reliable way of demonstrating a luteal-phase defect in conception cycles or early pregnancy as low levels of progesterone in early pregnancy are a reflection that the pregnancy has already failed because the trophoblast cannot produce sufficient progesterone. The use of colour-flow pulsed Doppler ultrasound may offer a non-invasive tool for diagnosis, and has been used in the diagnosis of luteal-phase defect, although only at a preliminary stage (Glock and Brumsted 1995).

There have been many reports of successful pregnancies following treatment with progesterone after the diagnosis of a luteal-phase defect. These studies have, for the most part, been uncontrolled. The only meta-analysis of controlled trials of progesterone treatment in women with recurrent miscarriage has not demonstrated any benefit (Daya 1989).

Treatment with hCG should stimulate progesterone production from the corpus luteum, and has been used in the treatment of luteal-phase defect. Although one small study demonstrated a beneficial effect of hCG treatment in women with oligomenorrhoea (Quenby and Farquharson 1994), meta-analysis has concluded that there is insufficient evidence at present concerning the effectiveness of hCG to rec-

ommend its use for women with unexplained recurrent miscarriage (Prendiville 1995).

Polycystic ovary syndrome and hypersecretion of luteinizing hormone

The prevalence of polycystic ovarian morphology in women with recurrent miscarriage is 40% (Rai et al 2000), and there have been numerous reports of an increased risk of miscarriage in women with hypersecretion of luteinizing hormone (LH), hyperandrogenaemia and, more recently, hyperprolactinaemia; all the classic endocrinopathies of polycystic ovary syndrome (PCOS) (Stanger and Yovich 1985, Howles et al 1987, Homburg et al 1988, Regan et al 1990, Bussen et al 1999). Nevertheless, a degree of controversy exists.

Several reports have not confirmed the relationship between hypersecretion of LH and an increased risk of miscarriage in women with recurrent miscarriage (Tulppala et al 1993, Liddell et al 1997). Whether this is due to the radioimmunoassays or a genetic variant of LH is unclear (Tulppala et al 1998). Also, suppression of high endogenous LH secretion with gonadotrophin-releasing hormone analogues in a prospective randomized placebo-controlled trial did not improve the livebirth rate (Clifford et al 1996).

The association between raised androgens and recurrent miscarriage has similarly not been confirmed with later studies (Liddell et al 1997, Rai et al 2000), although these are not universal findings and some studies have demonstrated retarded endometrial development and increased risk of miscarriage in association with raised testosterone levels (Tulppala et al 1993, Okon et al 1998).

Hyperprolactinaemia is a common finding in women with PCOS, and has also been associated with recurrent miscarriage (Hirahara et al 1998, Bussen et al 1999). Although one study has demonstrated a beneficial effect of bromocriptine treatment, this has not been corroborated elsewhere (Hirahara et al 1998).

In summary, PCOS is over-represented in women with recurrent miscarriage but the exact mechanism or individual endocrinopathy by which miscarriage is mediated remains unclear. Until this is determined, any corrective treatment is unlikely to be effective.

Autoimmune and thrombophilic factors

Autoimmune disease

Sporadic and recurrent miscarriage are recognized complications of systemic lupus erythematosus, the most common autoimmune disorder in women of reproductive age. Since the 1980s, it has been recognized that recurrent miscarriage is associated with an increase in the detection of many autoantibodies, even in asymptomatic women. The two most common groups of autoantibodies detected have been the antiphospholipid antibodies (aPL), which in conjunction with a history of recurrent miscarriage is now known as the 'antiphospholipid syndrome' (APS) (Harris 1987), and thyroid autoantibodies (Bussen and Steck 1995). However, with the exception of APS, the mechanisms by which a generalized increase in the autoantibody pool leads to miscarriage remain unclear. Although intravenous immunoglobulin (IVIG) therapy has been used in women with recurrent miscarriage associated with non-specific

autoimmunity, at present the collective evidence indicates that IVIG does not have a therapeutic effect that is clinically meaningful (Daya et al 1999).

Antiphospholipid syndrome

APS refers to the relationship between aPL, namely lupus anticoagulant (LA) and anticardiolipin antibodies (aCL), and recurrent miscarriage, thrombosis or thrombocytopenia (Harris 1987). Since this original description, it has become apparent that the three defining clinical features are too limiting, and aPL are implicated in a wide range of clinical conditions (Box 23.3).

In women with recurrent miscarriage, a previous personal or family history of thrombosis, cardiovascular disease, epilepsy and migraine is strongly predictive of a positive aPL status (Regan 1997). The overall prevalence of aPL in women with recurrent miscarriage is approximately 15% (Li 1998).

Women with APS without treatment have a miscarriage risk of 85–90%, the majority of which occur in the first trimester after establishment of a fetal heart (Rai et al 1995a,b). Pregnancy loss associated with APS is initially attributed to defective embryonic implantation and later to thrombosis of the uteroplacental vasculature and placental infarction (Rai and Regan 1998).

Diagnosis of APS and detection of aPL are subject to widespread interlaboratory variation and the fluctuating nature of the antibodies themselves. Testing for LA should follow internationally agreed guidelines (Lupus Anticoagulant Working Party on behalf of the BSCH Homeostasis and Thrombosis Task Force 1991), and the test of choice is the

dilute Russell's viper venom time which is more sensitive than the activated partial thromboplastin time and the kaolin clotting time. Testing for aCL is by standardized enzyme-linked immunosorbent assay. Testing must be repeated on at least two occasions 8 weeks apart in order to make a diagnosis of APS. Testing for aPL other than LA and aCL is of no clinical use in women with recurrent miscarriage.

Although a variety of treatments have been described for APS, including corticosteroids (Lubbe et al 1983), low-dose aspirin (Silver et al 1993), heparin alone (Rosove et al 1990) and IVIG therapy (Carreras et al 1988), treatment with subcutaneous heparin and low-dose aspirin until 34 weeks of gestation has been shown to be the most effective treatment for women with APS and recurrent miscarriage (Rai et al 1997). In cases where there are additional medical complications, such as thrombocytopenia, IVIG may be appropriate (Cowchock 1998, Piette et al 2000).

Other thrombophilic abnormalities

While APS is an acquired autoimmune thrombophilic state, recurrent miscarriage is also associated with other inherited and acquired causes of thrombophilia (Blumenfeld and Brenner 1999). Most studies are retrospective and interpretation must be cautious because of problems with acquisition and ascertainment.

Activated protein C resistance, usually but not always inherited via factor V Leiden mutation, is an important cause of acquired venous thrombosis and thrombophilia (Bertina et al 1994). It is also associated with recurrent fetal loss (Brenner et al 1997). Successful treatment with low-dose aspirin and heparin has been reported, although there are no prospective controlled studies to date.

Hyperhomocysteinaemia, as a result of congenital enzyme deficiencies or vitamin B6, B9 and B12 deficiencies, is associated with thrombosis and premature vascular disease (Boers et al 1985). It has also been reported in association with recurrent pregnancy loss (Wouters et al 1993). Thromboprophylaxis and vitamin supplementation have been reported (Aubard et al 2000), but no prospective data are yet available.

Other inherited thrombophilias, including protein S and protein C deficiency and antithrombin III deficiency, are associated with recurrent miscarriage as well as late pregnancy complications (Girling and de Swiet 1998). These need to be managed with appropriate haematological experience because of the increased risk of thromboembolism during pregnancy.

Screening women who have a history of recurrent miscarriage has shown increased incidence of thrombin generation — a global marker of a prothrombotic state — even when not pregnant (Vincent et al 1998). Further research is needed to determine whether thromboprophylaxis is appropriate for these women.

Alloimmune factors

The possibility that maternal alloimmune abnormalities lead to recurrent miscarriage has been proposed but remains contentious, and there is no reliable test. Treatments involving immunization with trophoblast or paternal leukocytes

- Multiple sclerosis

or third-party leukocytes have been successfully used in women with recurrent miscarriage. However, results of prospective randomized trials and meta-analyses have only shown minimal benefit or no benefit with treatment (Daya and Gunby 1994, Recurrent Miscarriage Immunotherapy Trialists Group 1994, Ober et al 1999). Any potential benefit must be balanced against the risk of the treatment, and at the present time, allogenic immunization should only be offered in the context of a clinical trial. Current recommendations, both in the UK and the USA, are against treatment.

Investigations

The known causes and management of recurrent miscarriage have been detailed above. Necessary investigations to identify such causes are indicated in women with recurrent miscarriage (Box 23.4). Testing thyroid function, random glucose, autoantibody screen and TORCH screen are no longer appropriate (Li 1998).

Women with recurrent miscarriage are best cared for by a careful history (ideally with a structured history sheet or questionnaire), thorough investigation, sympathetic explanation and counselling. This is best managed in the context of a dedicated recurrent miscarriage clinic. Women who conceive should then be offered early pregnancy clinic follow-up with ultrasonography and supportive care.

Treatment of unexplained recurrent miscarriage

Treatment of recurrent miscarriage where a potential cause has been identified has been discussed above. In approximately 50% of recurrent miscarriages, no cause is determined. The prognosis for this group is usually good. The value of continued reassurance and psychological support has been demonstrated (Stray-Pedersen and Stray-Pedersen 1984), with a 75% chance of a live birth in unexplained recurrent miscarriage. This support should include care in a specialist clinic, psychological support, easy access to a named contact, close monitoring including ultrasonography, appropriate reassurance, and helpful and caring staff.

Treatment of unproven value should not be offered. Any empirical treatment or treatment in clinical trials needs to have a sound scientific and statistical basis, and should

include careful counselling and informed consent (Clifford et al 1994, Liddell et al 1997).

Counselling

Counselling should be offered to all patients attending a recurrent miscarriage clinic. It should include an explanation of the possible underlying causes and prognoses. After three consecutive early pregnancy losses, there remains a 60–70% chance that the next pregnancy will be successful (Edmonds 1992, Li 1998). This chance decreases with each subsequent miscarriage, although even after six miscarriages, the chance of a successful pregnancy is still over 45%.

Conclusion

Recurrent miscarriage needs to be differentiated from sporadic miscarriage, and investigated thoroughly. Careful evaluation and treatment of this aetiologically diverse condition are necessary. Continued research into the causes and effective treatments is appropriate and best managed through a dedicated recurrent miscarriage clinic.

Sporadic miscarriage is common and increasing in incidence because of increasing maternal age. The majority of these are unlikely to recur. Management may involve expectant and medical treatment as well as surgical evacuation.

KEY POINTS

1. Miscarriage is the most common complication of pregnancy and accounts for the majority of emergency gynaecology consultations and admissions.
2. The term 'abortion' should be avoided and more sensitive terminology substituted.
3. Miscarriage is defined as the loss of an intrauterine pregnancy before 24 completed weeks of gestation.
4. Sporadic miscarriage occurs in approximately 15% of all clinically recognized pregnancies, and this rises with maternal age.
5. Most early miscarriages are the result of chromosomal abnormalities. The most common is trisomy.
6. Treatment of miscarriage is usually with surgical uterine evacuation, although medical and expectant management should be discussed. There is a small mortality rate with miscarriage, usually due to haemorrhage or sepsis.
7. Recurrent miscarriage is defined as three consecutive miscarriages. Recurrent miscarriage should be distinguished from sporadic miscarriage.
8. Recurrent miscarriage should be investigated and managed in a specialist clinic. Empirical treatments should be avoided.
9. All treatments for recurrent miscarriage need to be evaluated in controlled randomized prospective trials because of the high likelihood of live birth in any placebo group.

TREATMENT	355		

Introduction

The fallopian tube has many active roles in the process of reproduction. As the fallopian tube provides the environment in which fertilization and early development take place, these events may have a significant effect on all the subsequent events of the pregnancy. The role of the fallopian tube in the process of natural conception begins when the oocyte is released by the ruptured ovarian follicle and is picked up by the fimbrial end of the fallopian tube. It also facilitates the final maturation of sperm, which have passed through the uterus. Both the sperm and oocytes are transported within the fallopian tube to the site of fertilization and meet within well-defined, species-dependent time limits. Fertilization takes place at the ampullary-isthmic junction, and the pre-embryo is transported to the uterine cavity at the optimum time for implantation. Significantly, the sperm and pre-embryo, which differ antigenically from the mother, are not attacked by the immune system. The mechanisms by which all these complex processes are controlled are not well understood.

Ovum and embryo transport is probably the result of an interaction between the egg/embryo and the muscle contractions, ciliary activity and flow of tubal secretions. The relative importance of these factors is debatable, although there is evidence that ciliary activity plays a dominant role in gamete and embryo transport (Lyons et al 2006). Both myosalpingeal and ciliary activity are affected by a diverse range of chemical, biological and hormonal agents, including ovarian steroids, sympathomimetic agents, prostaglandins and angiotensin II (Jansen 1984, Saridogan et al 1996, Mahmood et al 1998).

Fallopian tubes probably act as sperm reservoirs, and this role may be essential for maintaining a certain number of sperm at the site of fertilization and preventing polyspermy by reducing the number of sperm available for fertilization. Sperm interaction with the tubal epithelium and secretions

may also play an important role in the preparation of sperm for fertilization (Saridogan and Djahanbakhch 2009).

Tubal secretions contain proteins that derive from the plasma and also some specific substances synthesized within the oviduct itself (Maguiness et al 1992a). Both tubal proteins and the physical contact between the gametes and the tubal epithelium may play a role in gamete function (i.e. capacitation), fertilization and early embryo development (Djahanbakhch et al 1994, Kervancioglu et al 2000).

Aetiology of Tubal Disease

Tubal disease is usually defined as tubal damage caused by pelvic infection such as pelvic inflammatory disease or tuberculosis, endometriosis, surgery or salpingitis isthmica nodosa, with varying degrees of tubal damage or obstruction, sometimes involving the adjacent ovary and the pelvic peritoneum, and adhesion formation. As a result, patients with tubal damage suffer from infertility and/or pelvic pain. This definition does not cover functional defects of the fallopian tube, as our ability to describe tubal disease is currently limited to demonstrating its patency and macroscopic normality. Tubal disease is accountable for 30–40% of cases of female infertility.

Salpingitis

Most salpingitis is the result of an ascending infection from the lower genital tract, caused primarily by *Chlamydia trachomatis* and *Neisseria gonorrhoeae* (see Chapter 61, Pelvic inflammatory disease, and Chapter 62, Sexually transmitted infections, for more information). These micro-organisms cause mucopurulent endocervicitis, and break down major cervical barriers, such as the mucus plug that protects the endometrium and upper genital tract, and permits ascending infection. Other pathogens such as *Streptococcus* sp., *Escherichia coli* and anaerobes ascend through the breached

barrier and reach the upper genital tract (Rice and Schachter 1991). In a significant proportion of cases, no aetiological agent is identified; this suggests that a range of other aetiological agents have a role, but the identification of novel organisms is difficult to ascertain because of the limited availability of diagnostic tests. Serological evidence has associated *Mycoplasma genitalium* with pelvic inflammatory disease (Simms and Stephenson 2009).

In the majority of patients, salpingitis is due to a sexually transmitted infection. In other cases, iatrogenic manoeuvres such as insertion of an intrauterine device, termination of pregnancy, hysterosalpingography or curettage can spread a cervical infection into the uterus and tubes. In a small proportion of women, pelvic infection may be secondary to gastrointestinal infections such as perforated appendicitis. *Mycobacterium tuberculosis* is still seen in developing countries; however, migration to developed countries has resulted in a significant increase in the number of tuberculosis notifications since the 1980s (Rose et al 2001).

Acute salpingitis causes loss of ciliated cells and distal occlusion of the fallopian tubes. Some of the deciliation may be recovered later, but subsequent immune response following the acute phase causes permanent scarring, loss of mucosal folds and flattening of the mucosa (Lyons et al 2006). Distal occlusion of the tubes together with chronic inflammatory process could result in fluid collection in the lumen of the fallopian tube, leading to hydrosalpinges. Pelvic peritonitis during the acute phase may be followed by adhesions around the fallopian tubes and ovaries, distorting the pelvic anatomy. Perihepatic inflammation may cause 'violin-string' adhesions known as 'Fitz-Hugh-Curtis syndrome' (Figures 24.1–24.3).

Other causes

Endometriosis, fibroids, previous pelvic/tubal surgery, salpingitis isthmica nodosa, endosalpingiosis and cornual polyps can be the cause of cornual obstruction or tubal damage. Endometriosis is reviewed in Chapter 33. In some patients, tubal damage is secondary to previous tubal or pelvic surgery such as salpingotomy for ectopic pregnancy, ovarian cystectomy, myomectomy, ovarian wedge resection and shortening of round ligaments. Salpingitis isthmica nodosa was described by Chiari (1887) as nodular thickening of the proximal part of the fallopian tube. The aetiology of this entity is unknown but it is probably due to a non-inflammatory process.

Diagnosis

Assessment of the fallopian tube should normally determine patency, a normal external and internal appearance, the ability to transport gametes and the embryo, and provision of an environment for the early steps of reproduction to occur. It is possible that, apart from the obvious need for tubal patency to allow passage of gametes, factors that affect the gametes and embryo, the effectors of tubal transport, the cilia, flow of tubal fluid and tubal contractions appear to constitute a higher-order system in which intact function of each may not be needed to achieve pregnancy (Verdugo 1986). However, dysfunction of this higher-order system

Figure 24.1 Laparoscopic view of a pelvis after pelvic inflammatory disease. There is a 'curtain' of adhesions covering the pelvic organs.

may be the reason for unsuccessful tubal surgery even when tubal patency has been achieved. Similarly, a functional disorder of this system may account for subfertility in some cases of unexplained infertility. Currently, tubal function is determined by demonstrating patency and normal appearance at laparoscopy.

The methods commonly used to determine tubal patency are hysterosalpingography (HSG), laparoscopy and hysterosalpingo contrast sonography (HyCoSy). The first two methods have been used for many years, whereas HyCoSy is a relatively new technique. All these methods have some degree of false-negative and false-positive results in determining tubal patency. A comparison of HSG and laparoscopy showed that complete agreement of tubal patency was found in 80.2% of cases (Maguiness et al 1992b). Laparoscopy has the ability to identify peritubal adhesions, endometriosis, polycystic ovaries, and other pelvic and intra-abdominal pathology. However, it is usually performed under general anaesthesia and does not give information about the uterine cavity. In general, these methods are considered complementary investigations, offering very important information (Figures 24.4–24.6). Laparoscopy also allows the surgeon to operate on abnormalities detected such as pelvic adhesions and endometriosis, provided that they have the relevant experience and the patient's consent has been obtained preoperatively.

The internal appearance of the fallopian tubes can be assessed by salpingoscopy. Salpingoscopy is the transabdominal examination of the tubal lumen by introducing an endoscope through the fimbrial end. Rigid endoscopes with a diameter of 2.8 mm allow excellent visualization of the infundibulum and ampulla as far as the ampullary–isthmic junction. The presence of minor intratubal lesions is not necessarily incompatible with fertility (Maguiness and Djahanbakhch 1992); however, loss of mucosal folds and intratubal fibrosis are significant. Nowadays, salpingoscopic assessment of the tubal lumen is recommended by some groups before tubal surgery for hydrosalpinges (Puttemans et al 1998). De Bruyne et al (1989) proposed a classification of ampullary findings in hydrosalpinges: grades 1 and 2 refer to normal salpingoscopic findings, grade 3 (intermediate group) refers to focal adhesions, and grades 4 and 5 refer to severe adhesions and loss of mucosal folds.

Transvaginal hydrolaparoscopy and fertiloscopy approaches utilize the advantages of laparoscopy but with a less invasive approach (Gordts et al 1998, Watrelot et al 1999). Transvaginal hydrolaparoscopy is the endoscopic examination of pelvic structures through the posterior vaginal fornix after instilling saline into the pouch of Douglas. This allows tubal patency to be checked, in addition to assessment of the pelvis for other pathology. Fertiloscopy includes salpingoscopy, microsalingoscopy and hysteroscopy for complete examination of the female reproductive tract. These procedures can be performed under local anaesthesia or sedation.

Selective transcervical salpingography and tubal catheterization can be done in cases where it is doubtful that there is cornual obstruction (Ataya and Thomas 1991). Mucus plugs and debris can be mobilized, and a tube that was apparently obstructed can be 'opened' following such a procedure.

Treatment

The treatment of tubal disease in the infertile patient includes selective salpingography with tubal cannulation, surgery and

Figure 24.5 Tubal cornual block. Irregular vessels seen on the peritoneum surface as a result of previous inflammation (arrow).

in-vitro fertilization-embryo transfer (IVF-ET). In comparison with the other two options, IVF is now widely used for the majority of patients with tubal disease. However, it is relatively expensive, labour intensive and carries risks of multiple pregnancy and ovarian hyperstimulation syndrome (see Chapter 22, Assisted reproduction treatments, for more information).

Selective transcervical salpingography

Selective transcervical salpingography and tubal catheterization can be used for the treatment of proximal tubal obstruction in selected cases. A review of the literature on fluoroscopic tubal cannulation showed pregnancy rates of 22.7% and ectopic pregnancy rates of 3.2% (Honore et al 1999).

Reconstructive tubal surgery

With the advent of IVF-ET, the role of reconstructive tubal surgery has diminished. However, this type of surgery is still appropriate and effective for properly selected individuals (National Institute for Clinical Excellence 2004). Initial methods for tubal surgery were based on microsurgical techniques. The use of magnification and microsurgical techniques has been the traditional method. However, with advances in laparoscopic surgery, most of these methods are now possible to perform at laparoscopy.

The criteria for patient selection for treatment depend very much on the surgeon's experience and on the possibility of being able to offer alternative treatment. Other points to be considered when making the decision regarding treatment are the patient's wishes about the type of treatment that she prefers and the problem of pain. Large numbers of patients with tubal disease have pelvic pain. In some of them, the surgical freeing of the ovaries and tubes from adhesions can give symptomatic relief.

Microsurgical treatment

The microscope was first used for tubal surgery by Walz (1959). Whilst others used delicate electrosurgery and magnification (loupes) in the treatment of hydrosalpinges, Paterson and Wood (1974) in Australia and Winston and McClure-Browne (1974) in England adapted their experience from animal experiments to humans and operated on infertile women, under high magnification, using an operating microscope.

Microsurgery is not only the use of a microscope; it is based on gentle tissue handling, reperitonealization of raw areas, the use of non-resorbable suture materials, and irrigation of the tissues using Ringer's lactate solution as this tends to prevent adhesion formation.

The use of the microscope was originally much debated, but microsurgery is now well established and is a routine procedure for tubal infertility.

Coadjuvants

The use of coadjuvants can sometimes help to avoid adhesion formation, but it is important to keep in mind that no coadjuvant will replace good surgical technique. Recent reviews of methods for preventing adhesions suggest that none of the methods have been clearly shown to improve

pregnancy rates; however, some methods such as steroids, oxidized regenerated cellulose (Interceed) and polytetrafluoroethylene (Gore-Tex) reduce adhesion formation (Metwally et al 2006, Ahmad et al 2008).

Cornual occlusion

Cornual occlusion due to inflammatory causes was treated by uterotubal implantation with very poor results. Ehrler (1963) described his technique and suggested that the intramural portion of the tube could be spared in most patients. Microsurgical methods described by Winston (1977) and Gomel (1977) became the surgical technique of choice. Cornual implantation is now rarely used. Tubocornual implantation is avoided whenever possible. Destroying a possible sphincter at the uterotubal junction is associated with excessive bleeding and damage to the tubal blood supply; it shortens the tube and may increase the risk of rupture of the uterus in the event of subsequent pregnancy, which means that patients must be delivered by caesarean section.

The use of magnification allows better identification of the intramural portion of the tube by careful shaving of the cornua until healthy tissue is found, permitting a more accurate tissue apposition with a watertight anastomosis between healthy tubal tissues. Once the ends are well defined, the anastomosis is done in two layers, using 8/0 nylon as a suture. The suture material should not penetrate the mucosa, only the muscularis (Seki et al 1977). In some cases, the use of a temporary splint gives considerable help, especially in deep cornual tubal anastomosis (Figure 24.7), but this should be removed at the end of the surgical procedure; if left *in situ*, the splint should not remain for more than 48 h as longer periods of time cause mucosal damage. Tension between the anastomosed ends must be avoided. A stitch of 6/0 Prolene between both ends of the mesosalpinx should be applied as a stay suture. More details about the technique have been given elsewhere (Winston 1977, Margara 1982).

Cornual polyps

Removal of cornual polyps is still a matter of controversy. Glazener et al (1987) stated that the removal of cornual polyps does not improve fertility and they are not a cause of infertility. However, consideration should be given to removal of large polyps present in the intramural or isthmic portion of the tube. This can involve salpingotomy and resection of the polyp without tubal resection or the opening of the cornu, and removal of the affected portion of the tube followed by cornual-isthmic anastomosis in two layers. In some cases when a large polyp is implanted deep in the intramural portion of the tube, the anastomosis can be difficult due to disparity of the lumen of the tubal ends. The portion where the polyp was present is wider than the isthmic portion of the tube, and it is not always easy to achieve a watertight anastomosis. For this reason, some surgeons prefer salpingotomy whenever possible.

Tubal anastomosis

Tubal anastomosis for reversal of sterilization is the most successful technique in microsurgery for the following

Figure 24.7 Cornual block diagram showing a cornual anastomosis. (A) Superficial cornual block. (B) Opening of the cornua to expose the intramural part of the tube. (C) Shaving of the tube to find healthy mucosa for anastomosis. (D) Cornual anastomosis completed.

reasons: healthy tissues are anastomosed, the localized damage is removed completely (Figure 24.8) and these patients are generally fertile.

Success depends on the length of the remaining tube. The minimum length of tube necessary to maintain fertility in women is not known. In animal experiments, fertility

Figure 24.8 Anastomotic procedure. (A) Both tubal lumens are exposed (healthy mucosa). (B) The first stitch is at 6 o'clock and must be extramucosal. (C) The anastomosis is completed in two layers. The suture material used is 8/0 nylon.

diminished in a linear fashion depending on the length of the ampulla resected; when more than 70% was missing, none of the animals became pregnant. Resection of the ampullary-isthmic junction did not appear to alter fertility (Winston et al 1977). The rabbit is far from an ideal model for human tubal physiology, but these results emphasize the fact that the ampulla seems to be important in maintaining fertility.

The length of time between sterilization and reversal is important and has a prognostic value. Vasquez et al (1980) demonstrated that after 5 years of sterilization, the proximal portion of the tube had a severely damaged mucosa with flattening of the epithelium and polyp formation. The surgical technique of reversal of sterilization has been described by Winston (1977) and Margara (1982).

Hydrosalpinges

As well as being a cause of infertility, hydrosalpinges also have a detrimental effect on the outcome of IVF-ET treatment, with reduced pregnancy and implantation rates and increased miscarriage rates. The hydrosalpinx fluid is known to be embryotoxic and may also reduce endometrial receptivity. Removal of hydrosalpinges prior to IVF-ET seems to lead to better results (Nackley and Muasher 1998, Zeyneloglu et al 1998). However, some groups believe that salpingectomy should only be performed when there is severe tubal pathology, and other patients should be given

the chance of tubal surgery (Puttemans and Brosens 1996). A Cochrane review concluded that further randomized trials are required to assess other surgical treatments for hydrosalpinx, such as salpingostomy, tubal occlusion or needle drainage of a hydrosalpinx at oocyte retrieval (Johnson et al 2004).

The value of microsurgery varies in the treatment of hydrosalpinges. In some cases, where the tube is completely free of adhesions, the use of loupes is sufficient. Where complex adhesions are present, the use of the microscope is beneficial. When performing a salpingostomy, the following points should be borne in mind. Before starting the salpingostomy, mobilization of the tube must be completed. Division of adhesions between tube and ovary or other pelvic organs is very important in order to leave the tube fully mobile, with the possibility of the new ostium being able to cover the whole ovarian surface and making egg pick-up more likely.

While dividing adhesions, special care must be taken to avoid damage to the fimbrial blood supply. These vessels are in the area of the connecting ligament between the ovary and the tube at the outer margin of the mesosalpinx. The hydrosalpinx must be opened at the most terminal part: the 'pucker point'. This is where the fimbrial end has closed; it is clearly seen under the microscope as a thin fibrous line, often with an H-shaped configuration, and is not always the thinnest part of the tube. Linear salpingostomy has a high chance of healing over. Using fine diathermy, the tube is opened and a glass probe is introduced, following the fibrous tracts parallel to the blood vessels and ensuring that the mucosal folds are not cut. Using small incisions, the new tubal ostium is completed and then the mucosa can be everted (Figure 24.9).

Two or three stitches of 8/0 nylon are used to secure the mucosal eversion. If the ovarian surface is damaged during the division of adhesions, the raw area is repaired using fine

non-absorbable suture material to avoid recurrence of adhesions.

Adhesions

Omental adhesions are not infrequent and when they are more than minimal, a partial omentectomy is performed. It is best done at the beginning of the operation. Fine 2/0 linen is used to secure the pedicles. It is not used as a routine procedure, but seems to be a very effective way of avoiding recurrent adhesions in the pelvis.

The most frequent adhesions are between the ampulla, the ovary and the mesosalpinx. It is easy to work from the isthmus towards the fimbrial end. Using a glass probe, the adhesions are hooked and incised with monopolar diathermy. Care should be taken not to damage the tubal peritoneum. The use of the microscope simplifies the process because the peritoneal edges can be seen easily. If the tubal peritoneum is incised, it must be repaired using 8/0 nylon as the suture material.

Ovarian adhesions should be removed from the ovarian capsule using diathermy or scissors, leaving the ovarian capsule as free as possible. Ovulation and egg release seem to improve after careful ovariolysis and may depend on the amount of the ovarian surface left free (Figure 24.10).

Special attention must be paid to raw areas. The uterine surface and the surrounding peritoneum must be inspected carefully. Peritonealization is very important and all raw areas must be covered. If the ovarian fossa has been damaged in order to free or liberate a firmly adherent ovary, the raw area should be closed using a linear suture of 4/0 Prolene. If the raw area cannot be peritonealized using the surrounding peritoneum, a peritoneal graft can be applied. The peritoneum should be thin and without fatty tissue. It is attached to the raw area using 8/0 nylon or 6/0 Prolene. The donor

(B) An incision is made using diathermy, and the tip of the glass probe is inserted into the hole in the tube. (C) The salpingostomy is enlarged using the diathermy needle and glass rods. (D) The salpingostomy is completed.

Figure 24.10 Laparoscopic appearance in a patient with severe periovarian adhesions after pelvic inflammatory disease.

areas can be the peritoneal layer of the anterior abdominal wall, the peritoneal space between the round ligament and the bladder and, in some cases, the peritoneum of the mesentery of the small or large bowel. This technique has proved very effective in experimental animals, and the results with humans are very encouraging. Synthetic materials are available to replace peritoneum (Hunter et al 1988, Haney and Dotty 1992). They can be applied during open surgery as well as laparoscopic procedures, and can remain *in situ*, apparently without side-effects; if removal is necessary, this can be done through a laparoscope.

It must be emphasized that the treatment of tubal damage due to tuberculosis is always medical and the tubal damage cannot be repaired by surgery. In this group of patients, if the uterine cavity remains unaffected or without damage, IVF is the only option.

Laparoscopic surgery

With the development of endoscopic techniques in the last three decades, gynaecologists, using a laparoscope, have been able to perform numerous operations in the field of infertility as well as in general gynaecology.

Since the first diagnostic use of the endoscope in the 1800s, developments in optics and related technology have revolutionized the use of the laparoscope. In the 1940s, Palmer in France promoted the laparoscope as a diagnostic instrument. In the 1970s, Gomel published the first results of laparoscopic surgery. He performed salpingo-ovariolysis and fimbrioplasties using this approach, with results comparable to those he achieved using magnification in open procedures. At the same time, Semm in Germany also developed the technique and a large number of new instruments became available for laparoscopic surgery.

The development of laser beams for medical use also had an impact in laparoscopic surgery. The use of video-laparoscopy has become a standard part of laparoscopic surgery. It is less tiring, and the assistant has a more active role during surgical procedures, thus it facilitates training and teaching. Different methods of dissection using laser diathermy (Donnez and Nisolle 1989) or cold cutting (Serour et al

1989) have been discussed. There is no evidence that one is better than the other.

After the initial experiences, procedures that can now be performed safely using operative laparoscopy include salpingo-ovariolysis, fimbrioplasty, salpingostomies, tubal reanastomosis, and management of ectopic pregnancy and endometriosis.

One of the most important attributes of this method is that it probably has a low rate of adhesion formation. There is no doubt that laparoscopic adhesiolysis is very effective for pain, and open surgery may cause more adhesion formation (Lundford et al 1991). The question still remains whether patients with severe tubal damage, not suitable for open procedures, should be operated upon using the laparoscopic approach when the prognosis is very poor and alternative methods are available to them.

Great financial advantages are offered by this method. This procedure can be done as a day case or overnight stay, and patients resume their normal activities in a very short period of time. Laparoscopic surgery, as with any other surgical procedure, has its risks and therefore intensive training is fundamental in order to diminish complications and achieve good results.

Results

Proximal tubal disease

Selective salpingography and tubal catheterization can achieve high patency rates and pregnancy rates of 49% (Honore et al 1999). With the exception of reversal of sterilization, laparoscopic surgery has a limited place in the treatment of proximal tubal disease. Microsurgical cornual anastomosis offers very good results in selected groups of patients. Postoperative laparoscopies show a high patency rate amongst those patients who have not conceived. The major limiting factors seem to be the recrudescence of the disease or extension of the original inflammation into the anastomotic site, rather than lack of patency. Gomel (1980) reported that 53% of patients conceived and had at least one term pregnancy.

Following tubocornual anastomosis by microsurgery, the reported term pregnancy rates in the literature vary between 22% and 57%, and ectopic pregnancy rates vary between 2% and 12%. These results are similar to cumulative delivery rates following five cycles of IVF-ET (Posaci et al 1999). In contrast, the outcome of tubouterine anastomosis is much poorer, and this procedure has mostly been replaced by tubocornual anastomosis.

The surgical treatment of salpingitis isthmica nodosa in the infertile patient is similar to that of cornual block. In nearly half of patients, the tubes are open and the diagnosis is made on the basis of the typical images of diverticulae on the hysterosalpingogram and at laparoscopy. The anastomotic procedure is generally much easier, but the length of isthmus portion that must be removed can be difficult to assess. The prognosis depends on the length of tube removed, but if insufficient tissue is removed, the surgical procedure is more likely to fail. The use of the microscope and the experience of the surgeon are very important in evaluation of the amount or length of tissue that must be resected. In

general, this condition involves most of the isthmic portion of the tube, so the anastomosis is between the cornu and the ampullary-isthmic junction.

Where the intramural portion of the tube is extensively involved in the process, the patient should probably not be treated surgically. The surgical procedure itself does not vary from that of tubocornual anastomosis. When the whole of the isthmus is removed, the problem of tension at the anastomotic level can be solved using stay sutures of 6/0 Prolene between the uterus and the mesosalpinx in order to approximate the tubal ends.

Reversal of sterilization

Reversal of tubal sterilization is the most successful procedure in tubal surgery. Both open microsurgical and laparoscopic reversals offer high pregnancy rates. The pregnancy rates in the literature following reversal of sterilization with microsurgery vary between 33% and 86%, with ectopic pregnancy rates of 1–14%. Pregnancy rates of up to 87.1% have been reported following laparoscopic reversal of sterilization (Yoon et al 1999). The success rates are lower after sterilization with cautery or Pomeroy's technique compared with clip or ring sterilization (Posaci et al 1999).

Salpingostomy

In general, it is difficult to assess the results of salpingostomy because a very heterogeneous group of patients is involved. Patient selection varies widely between units and there is no agreement regarding classification, especially where salpingostomy and fimbrioplasty are concerned.

Many gynaecologists think that salpingostomy is obsolete because IVF techniques offer comparable or better results in some cases. As in any other surgical procedure, good results will be achieved in well-selected patients.

Boer-Meisel et al (1986), in a prospective study, classified hydrosalpinges as grades I, II and III, based on the nature and extent of the adhesions, the microscopic aspect of the endosalpinx, the thickness of the tubal wall and the diameter of the hydrosalpinx. In their series, 77% of patients with grade I hydrosalpinx had the possibility of conception, compared with 21% with grade II and only 3% with grade III. Thus, surgery is the obvious treatment for patients with grade I hydrosalpinges. Patients with grade III hydrosalpinges should avoid salpingostomy and should be treated using IVF techniques after salpingectomy. The difficult group is that of grade II hydrosalpinx, where treatments with IVF or tubal surgery have the same prognosis. Age, social and religious background, the possibility of alternative treatment and the patient's wishes must be considered very carefully.

The success of tubal microsurgery for distal tubal lesions depends on several factors. Patients with extensive pelvic

adhesions, a thick tubal wall and abnormal tubal mucosa at salpingoscopy have poor results. Type of surgery also affects the outcome. Pregnancy rates as high as 59–60% can be achieved with fimbrioplasty, but the results after salpingostomy may not be as good (Posaci et al 1999). Patients with poor prognostic factors will have a higher chance of achieving pregnancy with IVF, whereas in the absence of poor prognostic factors, tubal microsurgery should be the first choice.

Laparoscopic surgery

Laparoscopic adhesiolysis for pelvic adhesions results in very good results, with term pregnancy rates of 47–62% and ectopic pregnancy rates of 4–8%. These results are similar to those achieved after microsurgery, so laparoscopic surgery should be the first option for suitable patients (Posaci et al 1999).

Success rates of laparoscopic surgery for distal tubal lesions also depend on several prognostic factors, including the presence of extensive pelvic adhesions, a thick tubal wall and severe endotubal damage. The reported intrauterine pregnancy rates following laparoscopic surgery for distal tubal lesions vary between 13% and 51%, with ectopic pregnancy rates of 3–23% (Posaci et al 1999). It appears that laparoscopic surgery offers similar success rates compared with microsurgery for lesser degrees of distal tubal damage. However, open microsurgery may be slightly better for more severe distal tubal disease. For the treatment of moderate to severe distal tubal disease, postoperative pregnancy rates are low, even after microsurgery, despite long periods of observation (>2 years), with remarkably high ectopic pregnancy rates. For this reason, IVF is preferable in these situations (Ozturk and Saridogan 2009).

Conclusion

Currently, in the absence of detailed information about early reproductive events which take place within the fallopian tube, the assessment of tubal function mainly depends on checking its patency and appearance at endoscopy. A better understanding of tubal physiology may enable us to test its function more effectively, and may also improve our understanding of so-called 'unexplained infertility'. There is no doubt that a large group of patients with tubal disease can be treated using IVF techniques. In a well-selected group of infertile patients with tubal damage, surgical procedures, performed using laparoscopy or open surgery (microsurgery), offer a very good prognosis and many patients can conceive more than once after a single treatment. In a highly specialized reproductive unit, these methods should be available and the choice of procedure should be adapted to each individual case.

KEY POINTS

1. Tubal disease is tubal damage caused by pelvic infection, endometriosis or iatrogenic disease with varying degrees of damage, and sometimes involving surrounding structures.
2. Tubal disease accounts for 30–40% of cases of female infertility.
3. Salpingitis most commonly results from ascending infection from the lower genital tract.
4. Salpingitis is not generally seen in women who are not sexually active.
5. *Chlamydia trachomatis* is responsible for a significant amount of salpingitis, postpartum endometritis and perihepatic adhesions.
6. Many organisms are capable of producing salpingitis. Chlamydia and gonococcal infections seem to pave the way for other micro-organisms to cross the cervical mucus and affect the uterus or tubes.
7. Although tubal damage of tuberculous origin is rare in developed countries, there has been an increase since the 1980s due to population migration.
8. A significant proportion of patients with tubal disease are best treated by IVF techniques.
9. In a well-selected group of infertile patients with tubal damage, surgical procedures, performed using laparoscopy or open surgery (microsurgery), offer a very good prognosis and many patients can conceive more than once after a single treatment.

Incidence

Ectopic pregnancy is defined as implantation of the fertilized ovum in a site other than the uterine endometrium. The incidence of ectopic pregnancy ranges between 0.25% and 1.5% of all pregnancies (including live births, medical termination of pregnancy and ectopic gestations). However, it varies geographically due to two reasons. Firstly, different denominators such as live births and reported pregnancies are used to express the results. Secondly, the exact incidence remains unknown as the diagnosis is often missed when the ectopic pregnancy resolves spontaneously at an early stage. Recently, the problem of ectopic pregnancies has been magnified by advancing maternal age, tubal surgery, pelvic inflammatory disease (PID) and assisted reproduction techniques.

In England and Wales between 1966 and 1996, the incidence of ectopic pregnancy increased 3.1-fold from 30.2 to 94.8 per 100,000 women aged 15–44 years, and 3.8-fold from 3.25 to 12.4 per 1000 pregnancies (Rajkhowa et al 2000). In the UK, for the 2003–2005 triennium, there were 11.1 [95% confidence interval (CI) 10.9–11.1] ectopic gestations per 1000 pregnancies reported (Lewis 2007).

In the USA, the Centers for Disease Control and Prevention have the most comprehensive data available on ectopic pregnancy. Between 1970 and 1989, there was a 5-fold increase in the incidence of ectopic pregnancies, from 3.2 to 16 per 1000 reported pregnancies (Goldner et al 1993). Women between 35 and 44 years of age have the highest risk of developing an ectopic pregnancy (27 per 1000 reported pregnancies). Data from the same centre indicate that the risk of ectopic pregnancy in African women (21 per 1000) is 1.6 times greater than the risk amongst Whites (13 per 1000); this is related to the high incidence of PID and low socioeconomic status in certain populations.

Ectopic pregnancy is still a cause of significant morbidity and mortality. In the UK, the number of deaths from ectopic

pregnancies has varied in the last decade: 12 (1994–1996), 13 (1997–1999), 11 (2000–2002) and 10 (2003–2005). The death rate for the 2003–2005 triennium was 0.35 (95% CI 0.19–0.64) per 100,000 estimated ectopic pregnancies. Seven of the 10 deaths due to ectopic pregnancies during this triennium were associated with failure to diagnose or substandard care (Lewis 2007). The risk of death is higher for racial and ethnic minorities, and teenagers have the highest mortality rates.

Aetiology and Risk Factors

The aetiology of ectopic pregnancy remains enigmatic. A common denominator in most theories is the delay in ovum transport. A likely consequence of the delay is that the ovum becomes too large to pass through certain areas of the fallopian tube, particularly the isthmus segment and the uterotubal junction. In addition, the growth and proliferation of the trophoblast may be so advanced that implantation of the fertilized ovum begins prior to the departure of the ovum from the fallopian tube. Myoelectrical activity of the wall of the fallopian tube allows approximation and fertilization of gametes, as well as propulsion of the zygote and cleaving embryo from the ampulla to the uterine cavity. Oestrogens increase smooth muscle activity and progesterone decreases muscular tone. The reported increased incidence of tubal pregnancy in perimenopausal women may be related to progressive loss of myoelectrical activity along the fallopian tube, which is observed with ageing.

The cilia of the tubal epithelium are also involved in transportation of oocytes towards the uterine cavity. Salpingitis results in loss of ciliated epithelium and subsequently delayed propulsion of the embryo/blastocyst towards the uterine cavity.

Steroid hormones, oestrogens and progesterone influence cilia formation and movements. Oestrogens stimulate epithelial cell hyperplasia and ciliogenesis. High levels of

Table 25.1 Risk factors for ectopic pregnancy

Pelvic inflammatory disease	Smoking
Medical termination of pregnancy	Diethylstilbestrol
Current intrauterine contraceptive device users	

serum progesterone are associated with deciliation and atrophy of the epithelium. These changes of the ciliated epithelium of the fallopian tube may explain the increased incidence of tubal pregnancy observed in women who take the progesterone-only pill or have a progesterone-containing intrauterine contraceptive device (IUCD) *in situ*.

All sexually active women are at risk of an ectopic pregnancy. The risk factors that may be associated with an ectopic pregnancy (Table 25.1) may be present in 25–50% of women.

Independent risk factors consistently shown to increase the risk of tubal pregnancy are discussed below.

Previous tubal pregnancy

A history of prior ectopic pregnancy is a significant risk factor. A woman who has experienced one ectopic pregnancy has a 10–20% chance of presenting with an ectopic gestation in her subsequent pregnancy. Accurate assessment of the risk of recurrent ectopic pregnancy is difficult because it depends upon the size, location of previous ectopic pregnancy, status of the contralateral adenexa, treatment method and history of subfertility.

Previous tubal surgery

Sterilization

Following sterilization, the absolute risk of ectopic pregnancy is reduced. However, the ratio of ectopic to intrauterine pregnancy is higher. The greatest risk for pregnancy, including ectopic pregnancy, occurs in the first 2 years after sterilization. The cumulative probability of ectopic pregnancy for all methods of tubal sterilization is 7.3 per 1000 procedures. Fistula formation and recanalization of the proximal and distal stumps of the fallopian tube are implicated for the occurrence of ectopic gestation. Women sterilized before the age of 30 years by bipolar tubal coagulation have a 27 times higher probability of ectopic pregnancy compared with postpartum partial salpingectomy (31.9 vs 1.2 ectopic pregnancies per 1000 procedures) (Peterson et al 1997). Tubal coagulation has a lower risk of pregnancy compared with mechanical devices (spring-loaded clips or fallope rings), but the risk of ectopic pregnancy is 10 times higher when a pregnancy does occur (DeStefano et al 1982).

Reversal of sterilization

The risk depends on the method of sterilization. Following reconstruction of a cauterized tube, approximately 15% of women who conceive have an ectopic pregnancy. The risk of ectopic pregnancy is reduced to 5% when the reversal is performed following Pomeroy's method or clip sterilization.

Tubal reconstruction and repair

Reconstructive tubal surgery is a predisposing factor for ectopic pregnancy. However, it remains unclear whether the increased risk results from the surgical procedure or from the underlying pathology of the ciliated tubal epithelium and pelvic disease. In a consecutive series of 232 tubal microsurgical operations, including salpingostomies, proximal anastomoses and adhesiolyses, 12 patients (5%) presented with an ectopic pregnancy whereas 80 patients (35%) achieved an intrauterine pregnancy (Singhal et al 1991). Silva et al (1993) reported a higher risk of recurrent ectopic pregnancy following conservative surgery of salpingostomy than radical surgery of salpingectomy (18% vs 8%, relative risk 2.38, 95% CI 0.57–10.01).

Pelvic inflammatory disease

The relationship between PID, tubal obstruction and ectopic pregnancy is well documented. Infection of tubal endothelium results in damage of ciliated epithelium and formation of intraluminal adhesions and pockets. A consequence of these anatomical changes is entrapment of the zygote and ectopic implantation of the blastocyst. Westrom et al (1981) studied 450 women with laparoscopically proven PID (case-control study). The authors reported that the incidence of tubal obstruction increased with successive episodes of PID: 13% after one episode, 35% after two episodes and 79% after three episodes. Following one episode of laparoscopically verified acute salpingitis, the ratio of ectopic to intrauterine pregnancy was 1:24, a six-fold increase compared with women with laparoscopically negative results.

Tubal damage induced by *Chlamydia trachomatis* is associated with tubal pregnancy. Many cases of chlamydia infection are subclinical.

Although PID is a high risk factor for ectopic pregnancy, it is pertinent to note that only 50% of fallopian tubes removed for an ectopic pregnancy have histological evidence of salpingitis.

Current intrauterine contraceptive device users

Unmedicated, medicated and copper-coated IUCDs prevent both intrauterine and extrauterine pregnancies. However, a woman who conceives with an IUCD *in situ* is seven times more likely to have a tubal pregnancy compared with conception without contraception (Vessey et al 1974). IUCDs are more effective in preventing intrauterine than extrauterine implantation. With copper IUCDs, 4% of all accidental pregnancies are tubal, whereas with progesterone-coated IUCDs, 17% of all contraceptive failures are tubal pregnancies. The different mechanisms of action of the two devices could partially explain the difference in failure rates. Although both devices prevent implantation, copper IUCDs also interfere with fertilization by inducing cytotoxic and phagocytotic effects on the sperm and oocytes. Progesterone-containing IUCDs are probably less effective in preventing fertilization. Although the incidence of pregnancy diminishes with long-term use of the IUCD, among women who become pregnant, the likelihood of ectopic pregnancy increases. Women who have used the IUCD for more than 24 months are 2.6 times more likely to have an ectopic pregnancy compared with short-term users (<24 months).

The 'lasting effect' of the IUCD may be related to the loss of the cilia from the tubal epithelium, especially if the IUCD has been *in situ* for 3 years or more (Wollen et al 1984, Ory HW 1981).

Termination of pregnancy

Data from two French case-control studies suggest that induced abortion may be a risk factor for ectopic pregnancy for women with no history of ectopic pregnancy. There is an association between the number of previous induced abortions and ectopic pregnancy [odds ratio (OR) 1.4 for one previous induced abortion and 1.9 for two or more] (Tharaux-Deneux et al 1998). Whether this is related to the spread of asymptomatic *C. trachomatis* infection or to the procedure itself is uncertain.

Assisted conception

Induction of ovulation with either clomiphene citrate or human menopausal gonadotrophin is a predisposing factor to tubal implantation (McBain et al 1980; Marchbanks et al 1985). A number of studies indicate that 1–4% of pregnancies achieved following induction of ovulation are ectopic pregnancies. The majority of these patients had a normal pelvis and patent tubes. The incidence of tubal pregnancy following oocyte retrieval and embryo transfer is approximately 4.5%. It must be noted that some women who undergo an in-vitro fertilization (IVF) cycle have risk factors for an ectopic pregnancy (i.e. previous ectopic pregnancy, tubal pathology or surgery).

Salpingitis isthmica nodosa

Salpingitis isthmica nodosa (SIN) is diagnosed by the histological evidence of tubal isthmic diverticula, and may be suggested by characteristic changes on hysterosalpingogram. Its incidence in healthy women ranges from 0.6% to 11%, but it is significantly more common in the setting of ectopic pregnancy. Persaud (1970) reported that 49% of fallopian tubes excised for tubal pregnancy had diverticula and evidence of SIN. The reason for the high incidence of ectopic gestation in women with SIN remains largely unknown. Defective myoelectrical activity has been demonstrated over the diverticula. Entrapment of the embryo into the diverticula is a possible mechanical explanation.

Smoking

A French study found that the risk of ectopic pregnancy is significantly higher in women who smoke. The risk increases according to the number of cigarettes per day (Bouyer et al 1998). The relative risk for ectopic pregnancy is 1.3 for women who smoke one to nine cigarettes per day, 2 for women who smoke 10–12 cigarettes per day, and 2.5 for women who smoke more than 20 cigarettes per day. Inhibition of oocyte cumulus complex pick-up by the fimbrial end of the fallopian tube and a reduction of ciliary beat frequency are associated with nicotine intake (Knoll and Talbot 1998).

Diethylstilboestrol

Results of a collaborative study indicate that the risk of ectopic pregnancy in diethylstilboestrol (DES)-exposed

women was 13% compared with 4% for women who had a normal uterus (Barnes et al 1980). A meta-analysis on risk factors for ectopic pregnancy confirms that exposure to DES *in utero* significantly increases the risk of ectopic pregnancy (Ankum et al 1996).

Pathology

Sites of ectopic pregnancy

A 21-year survey of 654 ectopic pregnancies (Breen 1970) revealed that the most common sites of ectopic pregnancy are as shown in Table 25.2. Similar distribution for tubal and abdominal pregnancy sites have been reported by Bouyer et al (2002) [ampullary (70.0%), isthmic (12.0%), fimbrial (11.1%), interstitial (2.4%), abdominal (1.3%)]. In this population, no cervical pregnancies were observed and slightly increased incidence was seen for ovarian pregnancies (3.2%) (Bouyer et al 2002).

Natural progression of a tubal pregnancy

Unruptured tubal pregnancy

Occasionally, in the very early stages of a tubal pregnancy, there are no obvious macroscopic features, and an ectopic pregnancy could be overlooked even after a laparoscopy. However, as pregnancy progresses, local enlargement of the tube occurs at the point of implantation. At a later stage, a large segment of the tube is distended and the tubal wall appears discoloured, dark red or purple.

Tubal rupture

One of the fundamental aspects of ectopic pregnancy is the inability of the tissues into which the blastocyst implants to offer resistance or respond to the invading trophoblast. Uncontrolled invasion of the trophoblast results in destruction of vessels, local haemorrhage and thinning of the tubal wall. Rupture of the tubal wall results in the escape of large amounts of blood, with or without the products of conception, into the peritoneal cavity. The embryo rarely survives. In rare cases, pregnancy continues if an adequate portion of the placenta is retained or if secondary implantation occurs in other organs of the pelvic or peritoneal cavity. Rupture occurs more often at the antimesenteric part of the tubal wall. Rupture of the inferior and mesenteric part of the tubal

Table 25.2 Sites of ectopic gestation

Fallopian tube	
Ampullary segment	80%
Isthmic segment	12%
Fimbrial end	5%
Interstitial and cornual	2%
Abdominal	1.4%
Ovarian	0.2%
Cervical	0.2%

wall results in haemorrhage between the two layers of the broad ligament. Intraligamentous haemorrhage could cause rupture of anterior or posterior layers of the broad ligament.

Spontaneous involution

Usually, the conceptus dies at an early stage without any notable symptoms.

Complete tubal miscarriage

At an early stage, the conceptus is extruded via the fimbriated end of the fallopian tube into the peritoneal cavity, and subsequently absorbed by the surrounding tissues.

Incomplete tubal miscarriage

The conceptus is partially extruded via the fimbrial end of the tube, and intervention is usually required.

Tubal blood mole or carneous mole

In some cases, recurrent choriodecidual haemorrhage around the dead conceptus contributes to the formation of a tubal blood mole or carneous mole. The presence and development of cellular and biochemical elements of connective tissue around the mole give rise to a semi-solid structure which could remain unresolved for years.

Time of rupture at various sites in the tube

Isthmic implantation

The isthmic segment of the fallopian tube is narrow and less distensible than the ampullary or interstitial segments. Isthmic rupture often occurs at 6–8 weeks of gestation and is usually dramatic.

Ampullary implantation

Rupture of an ampullary pregnancy usually occurs at 8–12 weeks of gestation. The ampulla is the wider segment of the fallopian tube and the site of 80% of all ectopic pregnancies.

Interstitial implantation

The interstitial segment of the fallopian tube is surrounded by myometrium which can hypertrophy to accommodate the enlarging conceptus. Rupture therefore occurs at a relatively late stage of 12–14 weeks of gestation. Rupture of an interstitial pregnancy causes damage of the highly vascularized cornual end of the uterus, resulting in severe intra-abdominal haemorrhage.

Histological changes

In the early stages of pregnancy, the myometrium responds in an identical pattern under the influence of hormones, irrespective of whether the gestation is ectopic or eutopic. The uterus becomes softened and slightly enlarged as a consequence of hypertrophy and hyperplasia of the myometrial cells. Where the gestation is ectopic, the endometrial glands

demonstrate an atypical histological pattern referred to as the 'Arias-Stella phenomenon', which is characterized histologically by: hyperplasia of glandular cells, closely packed glands with evidence of hypersecretion, large irregular hyperchromatic nuclei, cytoplasmic vacuolation and loss of cellular polarity. It is important to note that the Arias-Stella reaction is non-specific and can be found in the endometrium of patients with an intrauterine pregnancy. However, the presence of the Arias-Stella reaction and the absence of chorionic villi from endometrial curettings are both highly suspicious signs of an extrauterine pregnancy. The presence of chorionic villi is the most reliable histological feature for the definite diagnosis of pregnancy.

Simultaneous with the glandular changes, the stroma is converted into decidual tissue containing large polyhedral cells with hyperchromatic nuclei. A failing pregnancy and lower levels of associated hormones results in gradual disintegration of the decidua, giving rise to the intermittent, occasionally heavy, vaginal bleeding of uterine origin that occurs in ectopic pregnancy. In some cases, the decidua may be detached abruptly and passed as a flat, triangular, reddish-brown piece of tissue called a 'decidual cast'.

Diagnosis

Symptoms and signs

Ectopic pregnancy remains a diagnostic challenge. It should be considered as an important differential in any woman of reproductive age who presents with the triad of amenorrhoea, abdominal pain and irregular vaginal bleeding. This philosophy is particularly useful if the patient has any of the risk factor(s) identified in Table 25.1. The frequency with which various symptoms and signs were reported from a series of 300 consecutive cases are shown in Table 25.3 (Droegemueller 1982).

Abdominal pain

This is the most common symptom; however, it should be emphasized that there is no typical pain that is pathognomonic of ectopic pregnancy. Women can present with generalized abdominal or localized pain in the pelvis (unilateral or bilateral) and/or pain radiating to the shoulder.

The generalized abdominal pain is usually due to rupture of ectopic pregnancy and intraperitoneal haemorrhage. The pain is often severe. Shoulder pain is also an indirect indication of intraperitoneal haemorrhage. Accumulation of blood in the subdiaphragmatic region stimulates the phrenic nerve and creates shoulder tip pain. Localized pain may be due to distension of the fallopian tube. The pain may be sudden or progressive, and continuous or intermittent.

Amenorrhoea and abnormal uterine bleeding

Most patients present with amenorrhoea of at least 2 weeks duration. One-third of the women will either not recall the date of their last menstrual period or have irregular periods. Abnormal uterine bleeding occurs in 75% of women with an ectopic pregnancy. The bleeding is often light, recurrent and results from detachment of the uterine decidua. According to Stabile (1996a), 'If a patient who is a few weeks

Table 25.3 Symptoms and signs in 300 consecutive cases of ectopic pregnancy at admission

Symptoms and signs	Cases (%)
Abdominal pain	99
Generalized	44
Unilateral	33
Radiating to the shoulder	22
Abnormal uterine bleeding	74
Amenorrhoea ≤ 2 weeks	68
Syncopal symptoms	37

Unilateral adnexal mass	54
Uterus	
Normal size	71
6–8-week size	26
9–12-week size	3
Uterine cast passed away vaginally	7
Admission temperature $>37^{\circ}\text{C}$	2

pregnant complains of a little pain and heavy vaginal bleeding, the pregnancy is probably intrauterine, whereas if there is more pain and little bleeding, it is more likely to be an ectopic pregnancy'.

Other symptoms

Although abdominal pain, amenorrhoea and abnormal vaginal bleeding are the most common and typical symptoms, patients may present with additional features such as syncopal attacks. These are related to sudden-onset haemorrhage or to hypovolaemia or anaemia. Other atypical symptoms include diarrhoea or vomiting. In the 2003–2005 Confidential Enquiry into Maternal and Child Health report (Lewis, 2007), some women who presented with these symptoms were undiagnosed and subsequently died.

Physical examination

Physical examination should include an assessment of vital signs and examination of the abdomen and pelvis. Depending on the rate and amount of blood loss, the general condition of the patient may vary from slight pallor to haemodynamic shock. Palpation of the abdomen may reveal generalized or localized mild tenderness. Occasionally, guarding and rebound tenderness are also elicited.

An unusual feature is the Cullen's sign. This is bluish discoloration of the skin around the umbilicus caused by a considerable quantity of free blood in the peritoneal cavity. However, this sign is rare and its absence does not exclude massive intraperitoneal haemorrhage.

The findings on pelvic examination vary from completely negative examination to the presence of a large, fixed, soft

and tender mass. An adnexal mass may be palpable in up to 55% of cases. In many cases, the mass is ill defined and it may consist not only of tubal pregnancy but also of adherent omentum, small and large bowel. The mass may also be an enlarged corpus luteum. The uterus may be slightly enlarged but its size does not normally correspond to the gestational age. Cervical motion tenderness may or may not be present. A tender boggy mass in the pouch of Douglas, when present, represents either a collection of blood or a dilated tube adherent to the posterior uterine wall.

Types of presentation

The presentation of symptomatic patients with a tubal ectopic pregnancy may be acute or subacute.

Acute presentation

This is usually a consequence of rupture of the ectopic gestation and the ensuing intraperitoneal haemorrhage and haemodynamic shock. These symptoms are due to the intra-abdominal haemorrhage and collection of blood into the subdiaphragmatic region and pouch of Douglas. The patient is often pale, hypotensive and tachycardic. She may complain of shoulder tip pain or urge to defaecate. Abdominal examination reveals generalized and rebound tenderness. Vaginal examination will reveal tenderness in the adnexal region and cervical motion tenderness. However, vaginal examination in patients who present with an acute abdomen due to a ruptured ectopic pregnancy is generally considered unnecessary and potentially dangerous for the following reasons: (a) generalized haemoperitoneum and pain often mean that specific information cannot be elicited, (b) the patient is very uncomfortable and the assessment is often difficult and inadequate, and (c) it could result in total rupture of the ectopic pregnancy and delay management of the patient. Although it is reported that 30% of all women with an ectopic pregnancy present after rupture (Barnhart et al 1994), acute presentation is becoming less common. This is due primarily to increased patient awareness and early referral to the hospital for evaluation of 'suspected ectopic' pregnancies. Finally, the availability of more sensitive and rapid biochemical tests for beta-human chorionic gonadotrophin (β -hCG) quantification and the wider availability of transvaginal ultrasonography and laparoscopy have significantly reduced the interval between presentation and treatment.

Subacute presentation

When the process of tubal rupture or abortion is very gradual, the presentation of ectopic pregnancy is subacute. According to Stabile (1996a,b), this is the group of women who are symptomatic but clinically stable. A history of a missed period and recurrent episodes of light vaginal bleeding may exist. The circulatory system adjusts the blood pressure, and the patient is haemodynamically stable. Progressively increasing lower abdominal pain and, occasionally, shoulder pain are typical symptoms. On bimanual examination, there may be localized tenderness in one of the fornices, and cervical motion tenderness is often present. Subacute presentation occurs in 80–90% of ectopic pregnancies. In cases

with such a presentation, the establishment of an accurate diagnosis becomes more difficult, hence the need for further investigations.

Further Investigations

Biochemical tests

Quantitation of β -hCG subunit

hCG is a glycoprotein with a mass of 36,700 Da that is secreted by the syncytiotrophoblasts. It is heterodimeric, composed of two non-covalently linked α and β subunits. The α subunit is identical to that of follicle-stimulating hormone and luteinizing hormone, whereas the β subunit is specific to hCG. In response to β -hCG, the corpus luteum produces increasing concentrations of progesterone and other steroid hormones required to maintain early pregnancy, until the placenta takes over by the eighth week of gestation. β -hCG first enters the maternal circulation on the day of blastocyst implantation, i.e. 6–7 days after conception. Serum concentrations of β -hCG are approximately 1000 IU/l (third international standard) at approximately 4 weeks of pregnancy, increase exponentially during the first 6 weeks of gestation, and reach 20,000–250,000 IU/l at 10 weeks of gestation. Concentrations then decrease to 10,000–20,000 IU/l by 20 weeks of gestation and plateau thereafter.

Using highly sensitive assays (detection limit 0.1–0.3 IU/l), β -hCG can be detected in the maternal circulation around the time of implantation. This will appear in urine approximately 2 days after it appears in the blood. Most commercially available monoclonal-antibody-based urine pregnancy tests can detect β -hCG concentrations above 25 IU/l, which corresponds to day 24–25 of a regular 28-day cycle. The sensitivity of modern assays is 99–100%.

Single β -hCG measurement

A single serum β -hCG concentration has been used as a discriminatory level to detect an ectopic pregnancy as described below. A single measurement, however, has limited clinical value as there is considerable overlap of values for normal and abnormal pregnancies. When using radioimmunoassays with a detection limit of 5 IU/l, a single measurement of β -hCG may be useful because, if negative, it can exclude the diagnosis of an ectopic pregnancy.

Serial β -hCG measurements

Serum β -hCG concentrations double every 1.4–1.6 days from the time of first detection up to the 35th day of pregnancy, and then double every 2.0–2.7 days from the 35th to the 42nd day of pregnancy (Pittaway et al 1985). Since the normal doubling time of β -hCG is 2.2 days and its half-life is 32–37 h, serial quantitative assessments of β -hCG may help to distinguish normal from abnormal pregnancies. Kadar et al (1981) first reported a method for screening for ectopic pregnancy based on β -hCG doubling time. An increase in serum β -hCG of less than 66% over 48 h was suggestive of an ectopic pregnancy (using an 85% CI for

β -hCG levels). More recently, studies have used an increase in serum β -hCG levels of 35–53% (using 99% CI) to diagnose viable intrauterine pregnancies and to reduce the potential risk of terminating an intrauterine pregnancy (Seeber et al 2006). However, another method used to help with the diagnosis of an ectopic pregnancy is the 'plateau' in serum β -hCG levels. Plateau is defined as a β -hCG doubling time of 7 days or more (Kadar and Romero 1988). If the half-life of serum β -hCG is less than 1.4 days, spontaneous miscarriage is likely, whereas a half-life of more than 7 days is more likely to be indicative of an ectopic pregnancy. Therefore, falling levels of β -hCG can distinguish between an ectopic pregnancy and a spontaneous miscarriage. As a proportion of ectopic pregnancies are tubal miscarriages (with biochemical changes similar to those of intrauterine miscarriages), and approximately 15–20% of all ectopic pregnancies can have doubling serum β -hCG levels similar to those of normal intrauterine pregnancies (Silva et al 2006), suboptimal serial β -hCG changes are not specific or sensitive enough to diagnose ectopic pregnancies.

Serum progesterone

Progesterone, a C-21 hormone, is essential in early pregnancy for decidual function, implantation, reduction in immune response and myometrial quiescence. It is produced entirely by the corpus luteum until the sixth week of gestation. The trophoblastic contribution begins from the seventh week and becomes the predominant source by the 12th week. Progesterone concentrations continue to rise until 7 weeks of gestation and then plateau until 10 weeks, after which there is a gradual increase until term. In the conception cycle, progesterone concentrations are 2–4 nmol/l on the day of the luteinizing hormone surge and rise to 20–70 nmol/l a week later. At term, concentrations vary from 200 to 600 nmol/l.

Progesterone concentrations have been widely used for the diagnosis and management of pregnancies of unknown location (PUL, i.e. where ultrasound is inconclusive). In failing pregnancies, whether ectopic or miscarriage, progesterone concentrations are expected to be low compared with values in healthy ongoing pregnancies (Hahlin et al 1990). Most studies report cut-off concentrations of less than 16 nmol/l for failing pregnancies and more than 80 nmol/l for healthy ongoing pregnancies (Mathews et al 1986, Sau and Hamilton-Fairley 2003, Bishry and Ganta 2008). Progesterone levels over 25 nmol/l are 'likely to indicate' and levels over 60 nmol/l are 'strongly associated with' pregnancies subsequently shown to be normal. A progesterone concentration below 25 nmol/l in an anembryonic pregnancy has been shown to be diagnostic of non-viability (Elson et al 2003). Concentrations less than 20 nmol/l have a sensitivity of 93% and a specificity of 94% for the prediction of spontaneous resolution of PULs (Banerjee et al 2001). A meta-analysis has demonstrated that a single serum progesterone measurement is good at predicting a viable intrauterine or failed pregnancy, but is not useful for locating the site of pregnancy (Mol et al 1998). When interpreting progesterone measurements, variations in concentrations should be taken into account because of the assay methods, and a departmental protocol should state the normal range for that unit.

Other protein and steroid markers

In an effort to detect an ectopic pregnancy at an early stage, various steroid and protein markers have been studied including Schwangerschafts protein-1, human placental lactogen, pregnancy-associated plasma protein A, inhibin and insulin growth factor binding protein-1. However, none of these markers has been found to make a significant impact on clinical practice. Recently, serum CA125, creatine kinase, activin A and vascular endothelial growth factor have also been studied for the diagnosis of ectopic pregnancy; however, their sensitivity and specificity are not sufficient to allow their application in clinical practice.

Ultrasonography

Ultrasound has become an essential tool in the assessment and diagnosis of suspected ectopic pregnancies. The presence of an intrauterine pregnancy does not conclusively exclude an ectopic pregnancy; however, the occurrence of a heterotopic pregnancy is rare. The transvaginal approach is far superior to the abdominal approach, as the proximity of the vaginal probe to the pelvic structures and the use of high-frequency transducers (5–7 MHz) significantly improves resolution.

The earliest a normal intrauterine gestational sac (approximately 2 mm) can be seen is 4 weeks with a transvaginal ultrasound and 5 weeks with an abdominal ultrasound. In 20% of patients with an ectopic pregnancy, collection of fluid within the uterine cavity results in the formation of a pseudo gestational sac which mimics a true intrauterine sac. Ultrasonographic signs of a true gestational sac include an eccentrically placed gestational sac within the uterine cavity, the double ring or double decidual sac sign (DDSS) and an intact midline endometrial echo, with the pregnancy seen implanted beneath the endometrial surface. The double ring comprises chorionic villi, intervillous lakes, the extravillous trophoblast and the maternal decidua. This DDSS can also be seen in one-third of ectopic pregnancies. On the other hand, a pseudo sac is surrounded by a single layer of tissue, tends to follow the contour of the cavity, and in a longitudinal section of the uterus, the midline endometrial echo cannot be seen because of the fluid.

The most reliable sign to differentiate between a pseudo sac and a true sac is the appearance of a yolk sac within the true gestational sac. The yolk sac confirms an intrauterine pregnancy even before a live embryo is detected. A yolk sac is identified by ultrasound when the mean gestational sac diameter is greater than 8 mm.

A review of the literature by Brown and Doubilet (1994) revealed the frequency of various ultrasound features in ectopic pregnancies as detailed below:

- an empty uterus (28%);
- an empty uterus and an adnexal mass (35%);
- an intrauterine sac or pseudo gestational sac (25%);
- an empty uterus and an ectopic gestational sac (12%) with or without a yolk sac and cardiac activity; and
- varying amount of fluid in the pouch of Douglas (25%).

In ectopic pregnancies, a hyperechogenic tubal ring ('doughnut' or 'bagel' sign) is the most common finding on

ultrasound scan. Others include a mixed adnexal mass representing either tubal miscarriage or tubal rupture, an ectopic sac with a yolk sac, or an embryo with or without a fetal heartbeat. The corpus luteum may be present on the ipsilateral side in 85% of cases. It has been reported that 74% of ectopic pregnancies can be visualized on initial transvaginal ultrasound scan, and more than 90% of ectopic pregnancies can be visualized prior to treatment (Kirk et al 2007).

Quantitative assessment of β -hCG levels is essential for the accurate interpretation of ultrasonographic findings. A single serum β -hCG measurement has been used as a discriminatory level to help with the diagnosis of ectopic pregnancy. Absence of an intrauterine gestational sac with serum β -hCG levels of 6500 IU/l or more has an 86% positive predictive value and a 100% negative predictive value for the presence of an ectopic pregnancy (Romero et al 1985). With transvaginal ultrasound scan, different discriminatory levels of serum β -hCG (e.g. 1000, 1500 and 2000 IU/l) have been used with no significant difference in the detection rates of ectopic pregnancies (Barnhart et al 1999, Condous et al 2005). Failure to visualize an intrauterine gestational sac by transvaginal ultrasound if β -hCG concentrations are 1000–2000 IU/l or more indicates either an abnormal intrauterine pregnancy, a recent miscarriage or an ectopic pregnancy. It must be emphasized that although the discriminatory zone for an intrauterine pregnancy is well established, there is no such discriminatory zone for ectopic pregnancies. In 15–20% of women with clinical suspicion of an early pregnancy failure, ultrasound findings are not diagnostic.

Doppler ultrasonography

Doppler ultrasound is a non-invasive biophysical method of investigating patterns of blood flow. In ectopic pregnancies, the normal high-resistance blood flow in the uterine or ovarian artery branches changes to low resistance.

Jurkovic et al (1992), in a prospective study, used colour Doppler to detect and compare changes of blood flow in the uterine and spiral arteries and the corpus luteum in ectopic and intrauterine pregnancies. In intrauterine pregnancies, the impedance to flow (resistance index) in uterine arteries decreased with gestational age, but this remained constant in ectopic pregnancies. Peak blood velocity in the uterine arteries increased with gestational age in intrauterine pregnancies, and the values were significantly higher than those seen in ectopic pregnancies. However, uterine blood flow velocity was lower in the ectopic group, indicating an overall reduction in uterine blood supply. Local vascular changes associated with a true gestational sac differentiate an intrauterine pregnancy from the pseudo sac of an ectopic pregnancy. Doppler flow imaging may thus suggest that an adnexal mass is an ectopic pregnancy from the presence of high vascularity at the periphery of the adnexal mass.

Colour and pulsed Doppler increase the sensitivity of transvaginal ultrasound and allow earlier detection of ectopic pregnancies, thereby giving the opportunity for the application of medical treatment or conservative surgery.

Three-dimensional ultrasonography

Three-dimensional (3D) ultrasound is emerging as a possible additional diagnostic tool for ectopic pregnancy. Rempen

(1998) conducted a prospective follow-up study in order to evaluate the potential of 3D ultrasound to differentiate intrauterine gestations from extrauterine gestations. Fifty-four pregnancies with a gestational age of less than 10 weeks and with an intrauterine gestational sac more than 5 mm in diameter were included in the study. The configuration of the endometrium in the frontal plane of the uterus was correlated with pregnancy outcomes. It was found that this configuration was asymmetrical in 84% of intrauterine pregnancies, whereas the endometrium showed asymmetry in 90% of extrauterine pregnancies ($P \leq 0.0001$). The conclusion was that evaluation of the endometrial shape in the frontal plane may be a useful additional means of distinguishing intrauterine from extrauterine pregnancies.

Harika et al (1995) conducted a study to assess the role of 3D imaging in the early diagnosis of ectopic pregnancy on 12 asymptomatic patients whose gestational age was less than 6 weeks. Nine of these patients had an ectopic pregnancy at laparoscopy, and of these, 3D transvaginal ultrasound showed a small ectopic gestational sac in four cases. These preliminary results suggest that 3D ultrasound may be an effective procedure for the diagnosis of ectopic pregnancy in asymptomatic patients prior to the sixth gestational week; however, its accuracy would have to be refined.

Diagnostic laparoscopy

With the availability of sensitive quantitative serum β -hCG assays and high-resolution transvaginal ultrasound, diagnostic laparoscopy is seldom used nowadays as a primary diagnostic tool. In some units, it is used to diagnose ectopic pregnancy in the presence of an empty uterus with serum β -hCG levels above the discriminatory level. A major disadvantage of laparoscopy is that a small ectopic pregnancy may not be visualized, and in 3–4% of cases the diagnosis will be missed. Therefore, careful selection of patients is crucial.

Culdocentesis

With the availability of modern equipment and biochemical tests, culdocentesis is rarely used for the diagnosis of ectopic pregnancy. However, in parts of the world where these facilities are lacking, aspirating blood from the pouch of Douglas which does not clot on standing is most likely suggestive of an ectopic pregnancy.

Differential Diagnosis

The differential diagnoses of an ectopic pregnancy should include ruptured corpus luteum cyst, threatened or incomplete miscarriage, PID and degenerating fibroids. Quantitative assessment of β -hCG, transvaginal ultrasonography and laparoscopy are powerful tools which should be used to resolve uncertain cases.

Pregnancy of Unknown Location

In recent years, PUL has been used as a diagnosis for patients with a positive pregnancy test with no signs of intrauterine or extrauterine pregnancy or retained products of conception on an initial transvaginal ultrasound scan. Studies report

that PUL is identified in 8–31% of women referred for ultrasound assessment in early pregnancy (Hahlin et al 1995, Condous et al 2004).

Subsequent follow-up in woman with PUL will lead to the diagnosis of either: (a) an intrauterine pregnancy that was too early to be visualized on an initial ultrasound scan; (b) an ectopic pregnancy that was too early to be visualized or was missed on an initial ultrasound scan (7–20%); (c) a spontaneously resolving pregnancy known as a 'failing PUL' (50–70%), which would include both intrauterine and extrauterine pregnancies; or (d) persistent PUL, where biochemical findings mimic an ectopic pregnancy with suboptimal serum β -hCG levels that fail to decline, and failure to localize pregnancy on ultrasound scan or laparoscopy.

PULs present a management dilemma for health professionals in the early pregnancy unit, and inevitably increase workload and time consumption. For clinically stable women, expectant management has been demonstrated to be safe. PULs are followed up with serial hormone measurements, repeat transvaginal ultrasound scans and possibly laparoscopy with or without uterine curettage. It is important to note that in women with a history and transvaginal ultrasound findings suggestive of complete miscarriage, serial β -hCG measurements should be performed as approximately 6% of these can be ectopic pregnancies (Condous et al 2004b).

Recently, the use of β -hCG ratios (β -hCG 48 h/ β -hCG 0 h) rather than absolute β -hCG values has been assessed in the diagnosis and management of PUL. A β -hCG ratio below 0.87 (or a β -hCG decrease >13%) has a 92.7% sensitivity (95% CI 85.6–96.5) and a 96.7% specificity (95% CI 90.0–99.1) for the prediction of a failing pregnancy (Condous et al 2006, Bignardi et al 2008). Various mathematical models using log regression and the Bayesian approach have been developed to predict the outcome of PULs; however (Condous et al 2004), these need to be tested prospectively in multicentre trials. Figure 25.1 shows an algorithm for the management of women with PUL.

Management of Ectopic Pregnancy

Figure 25.2 shows a summary of the algorithm for managing ectopic pregnancies. The following section should be read in tandem with this figure.

Surgical treatment

Laparoscopy or laparotomy

All the surgical procedures for the treatment of ectopic pregnancy can be accomplished via laparoscopy or laparotomy. The main factors which will determine the preferred approach are:

- haemodynamic condition of the patient;
- size and location of the ectopic pregnancy;
- laparoscopic experience of the surgeon; and
- availability of appropriate equipment for laparoscopic surgery.

Laparotomy should be considered where the patient is haemodynamically unstable, there is a suspicion of extensive abdominal and pelvic adhesions making laparoscopy

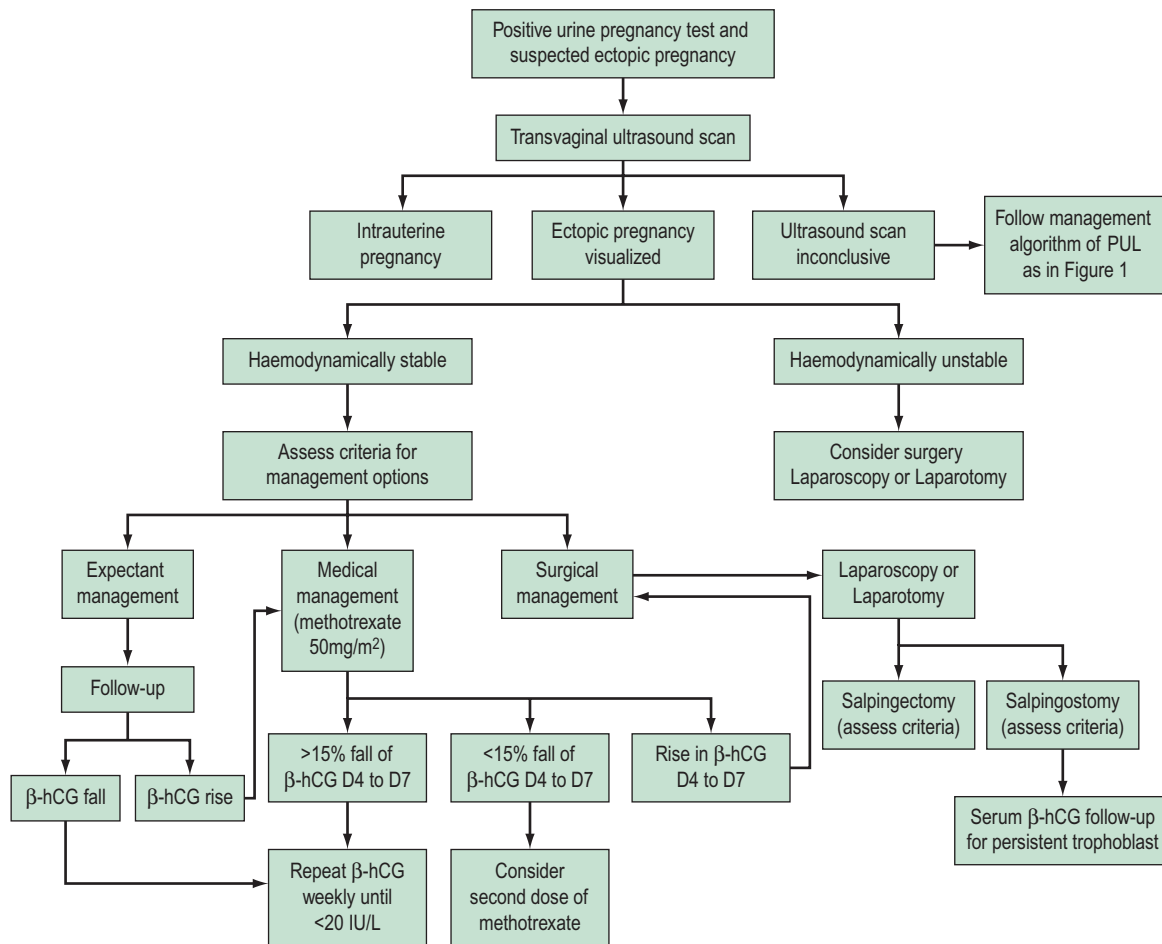

Figure 25.1 Algorithm for the management of women with pregnancy of unknown location (PUL). β -hCG, beta human chorionic gonadotrophin.

difficult, or the pregnancy is cornual or ovarian. A ruptured ectopic pregnancy does not necessarily require laparotomy, the main aim being use of the most expedient method. In the hands of an experienced laparoscopist, all the indications for laparotomy are relative rather than absolute.

A systematic review has shown that laparoscopic salpingostomy is significantly less successful than the open surgical approach in the elimination of tubal ectopic pregnancy (two randomized controlled trials, $n = 165$, OR 0.28, 95% CI 0.09–0.86) due to a significantly higher persistent trophoblast rate in laparoscopic surgery (OR 3.5, 95% CI 1.1–11). However, the laparoscopic approach is significantly less costly than open surgery. Long-term follow-up ($n = 127$) shows no evidence of a difference in intrauterine pregnancy rate, but there is a non-significant tendency to a lower repeat ectopic pregnancy rate (Hajenius et al 2007). The laparoscopic approach is associated with less intraoperative blood loss, lower analgesic requirements and a shorter duration of hospitalization and convalescence. An additional benefit of the laparoscopic approach is significantly fewer adhesions at the surgical site compared with those treated by laparotomy (Lundorff et al 1991).

Salpingectomy

Removal of the fallopian tube is still the most common method for the treatment of ectopic pregnancy. It can be

performed via laparotomy or laparoscopy. When laparotomy is performed, the easiest way to remove the fallopian tube is by progressive division and ligation of the mesosalpinx. Laparoscopic salpingectomy can be performed with a pretied loop ligature, bipolar diathermy or disposable stapling devices. However, the cost associated with the use of the stapling devices has limited their popularity.

Several methods have been proposed for removal of the fallopian tube from the peritoneal cavity following laparoscopic salpingectomy:

- placement of the fallopian tube into a specially designed plastic bag introduced via a 10-mm port. The bag is then sealed at its neck and removed intact through the port;
- morcellation of the fallopian tube and removal by a 10-mm grasping forceps; or
- posterior colpotomy and removal of the tube intact via the pouch of Douglas.

When to consider salpingectomy

Salpingectomy is indicated for women with:

- ruptured tubal pregnancy;
- recurrent ectopic pregnancy in a tube already treated conservatively;
- previous sterilization and reversal of sterilization;

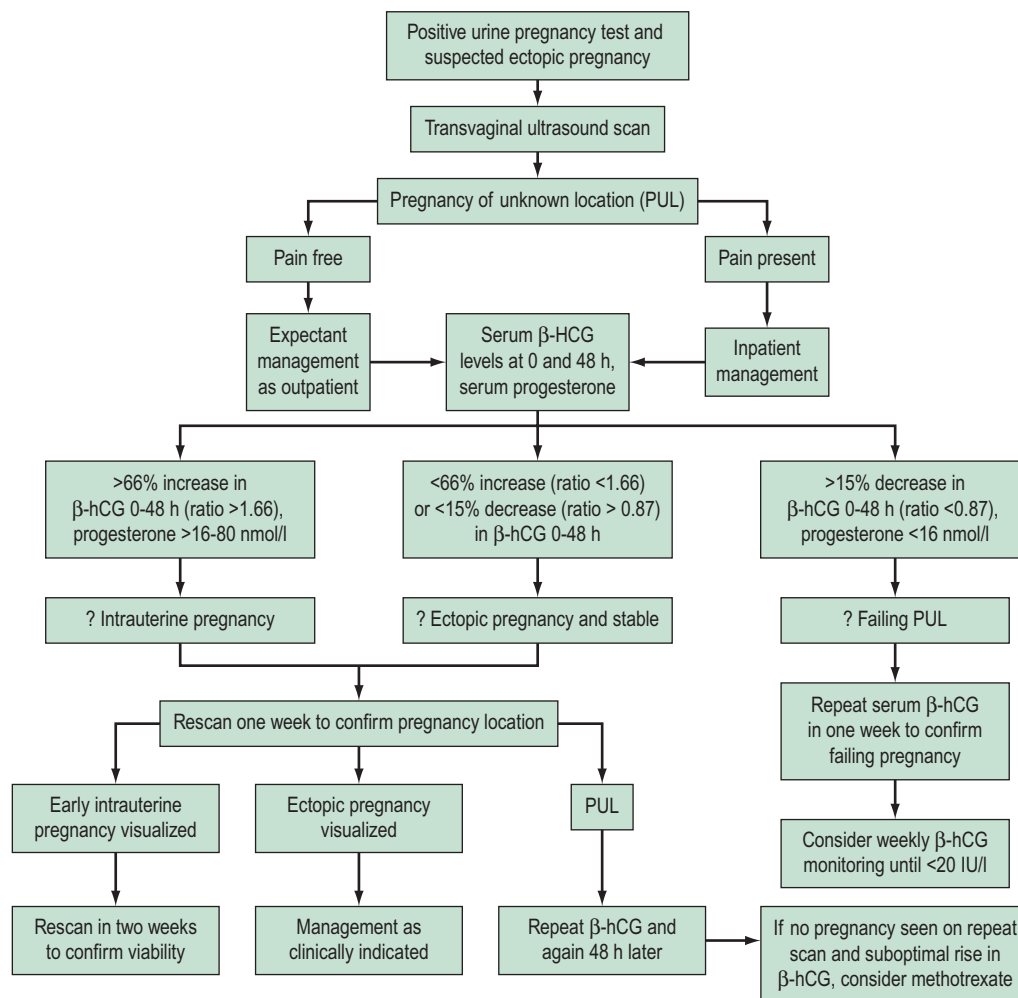

Figure 25.2 Algorithm for management of ectopic pregnancies. PUL, pregnancy of unknown location; β -hCG, beta human chorionic gonadotrophin; D4, day 4; D7, day 7.

- previous tubal surgery for infertility; or
- pre-existing tubal damage as a consequence of a frozen pelvis.

No randomized controlled trials have compared salpingectomy and salpingotomy. Results from four cohort studies suggest that there may be a higher subsequent intrauterine pregnancy rate associated with salpingotomy, but the magnitude of this benefit may be small (Royal College of Obstetricians and Gynaecologists 2004). The possibility of further ectopic pregnancies in the conserved tube should also be discussed if salpingotomy is being considered. In the presence of a healthy contralateral tube, there is no clear evidence that salpingotomy should be used in preference to salpingectomy.

Finally, the debate over salpingectomy or salpingo-oophorectomy no longer exists. Removal of a healthy ovary is now considered both unnecessary and unjustified.

Linear salpingotomy

An incision is made on the antimesenteric border of the fallopian tube with either a needle-point monopolar cutting diathermy, scalpel, scissors or laser, and the tubal lumen is exposed. The products of conception are removed with

grasping forceps. Sometimes the laparoscopic suction/irrigation probe may be used for aqua dissection and removal of the products of conception by suction. Irrigation of the tubal lumen after removal of the products of conception is essential. Thereafter, haemostasis is achieved with electrocoagulation. The incision can either be closed with a fine non-absorbable suture material such as 6/0 Prolene, or left open (salpingotomy) for healing to occur by secondary intention. Either approach results in satisfactory healing of the tubal wall. A study by Tulandi and Guralnick (1991) showed that there was no significant difference in the number of subsequent intrauterine pregnancies, number of ectopic pregnancies or incidence of adhesion formation with either method.

Linear salpingotomy can be performed via an open or laparoscopic approach. However, regardless of the route used to access the ectopic pregnancy, the surgeon should remember that fallopian tubes are delicate structures. Basic microsurgical principles such as gentle handling of tissues, avoidance of peritoneal damage, thorough irrigation and suction of the peritoneal cavity to remove all the blood clots, and minimizing postoperative adhesion formation should always be applied.

Laparoscopic linear salpingotomy should be considered as the primary procedure of choice for the treatment of tubal

ectopic pregnancy in the presence of contralateral tubal disease and where the patient wishes to retain her potential for future fertility.

The use of conservative surgery exposes the women to a small risk of tubal bleeding in the immediate postoperative period, persistent trophoblast and the risk of subsequent ectopic pregnancy in the conserved tube. For identification and treatment of persistent trophoblast, these women should be followed by serial β -hCG measurements post surgery. Treatment with methotrexate can be initiated if β -hCG concentrations fail to fall as expected. Sauer et al (1997) initiated treatment if serum β -hCG was more than 10% of the preoperative level by 10 days after surgery, and Pouly et al (1991) initiated treatment if serum β -hCG was more than 65% of the initial level at 48 h post surgery. Currently, there is insufficient evidence to recommend ideal cut-off concentrations of serum β -hCG for commencing treatment, but protocols for identification and treatment of persistent trophoblast should be present in every unit.

Segmental resection

When the ectopic pregnancy is located in the isthmic segment of the fallopian tube, segmental resection and end-to-end anastomosis constitute one of the conservative surgical therapeutic options. The anastomosis is usually isthmoampullary and can be performed either at the time of the resection (primary) or at a later stage (secondary). However, for isthmic tubal pregnancy, linear salpingotomy is technically less difficult and has a shorter operative time.

Fimbrial evacuation

Fimbrial evacuation is indicated when the pregnancy lies in the fimbrial segment of the fallopian tube. It involves gentle and progressive compression of the tube, starting just proximal to the side of the pregnancy and moving it systematically to the fimbrial end of the tube. When the pregnancy is located at the ampullary part, fimbrial evacuation or 'milking of the tube' is not recommended. The external pressure required to propel the ectopic pregnancy and achieve a tubal miscarriage is likely to cause severe damage to the endosalpinx and excessive bleeding from the implantation site, and the procedure is associated with a greater risk of persistent trophoblastic disease (Brosens et al 1984). When milking was compared with linear salpingotomy for ampullary ectopic pregnancy, milking was associated with a two-fold increase in the recurrent ectopic pregnancy rate (Smith et al 1987).

Reproductive outcome

The evaluation of reproductive outcome following surgical treatment for ectopic pregnancy is based on three main parameters:

- tubal patency as assessed by hysterosalpingography or second-look laparoscopy;
- subsequent intrauterine pregnancy rate; and
- recurrent ectopic pregnancy rate.

In patients who underwent radical surgery (salpingectomy), the subsequent intrauterine pregnancy rate was 49.3% (range 36.6–71.4%) and the recurrent ectopic preg-

nancy rate was 10% (range 5.8–12%). In patients who underwent conservative surgery, the subsequent intrauterine pregnancy rate was 53% (range 38–83%) and the recurrent ectopic pregnancy rate was 14% (range 6.4–21.2%). These results are based on a retrospective analysis of nine studies in a total of 2635 patients, and indicate that conservative surgery is associated with higher subsequent intrauterine pregnancy and higher recurrent ectopic rates compared with radical surgery (Yao and Tulandi 1997). However, the variations in the design of each study make strict comparison of the results very difficult. Similar figures of intrauterine pregnancy (83.7%) and recurrent ectopic pregnancy (8%) have been reported when expectant management is compared with salpingectomy (Helmy et al 2007).

Medical treatment with methotrexate

Early detection of an ectopic pregnancy, the desire to retain fertility, and minimizing costs and surgical morbidity are the main reasons for incorporating medical treatment as an option for managing ectopic pregnancies. The most frequently used drug is methotrexate and this will therefore be discussed in detail, although other agents have been used. Gynaecologists are familiar with methotrexate because the drug has been used very effectively for the treatment of gestational trophoblastic disease since 1955 (Li et al 1956). Hreschchyshyn et al (1965) were the first to report on the use of methotrexate in the management of ectopic pregnancy. In 1982, Tanaka et al reported on the treatment of an unruptured interstitial pregnancy with a course of intramuscular methotrexate.

Mode of action and pharmacokinetics

Methotrexate, formerly known as amethopterin, is a potent folic acid antagonist. It inhibits the action of the enzyme dehydrofolate reductase and the coenzyme methyl tetrahydrofolate. These enzymes are essential for the conversion of dehydrofolic acid into tetrahydrofolic acid, and the conversion of deoxyuridylic acid into thymidylic acid which is critical for the synthesis of DNA during the S phase of the cell cycle. Prevention of incorporation of thymidylic acid into DNA results in lack of DNA synthesis and subsequent arrest of cellular division and multiplication. Methotrexate is ideal for inhibition of rapidly growing cells such as trophoblasts.

Methotrexate is almost completely absorbed if administered intramuscularly, with peak serum concentrations reached within 30–60 min. Only 10% of methotrexate undergoes hepatic and intracellular metabolism to polyglutamated products, which also act as active antimetabolites. Up to 90% of the drug is secreted unchanged in the urine within 48 h, and therefore impaired renal function can result in prolonged exposure of tissues to high levels of methotrexate or its metabolic products.

Side-effects of methotrexate

The two most significant factors that determine the intensity of methotrexate toxicity are the serum concentration of drug and the duration of exposure to methotrexate. The drug affects all rapidly proliferating cells, and therefore the main

side-effects originate from suppression of bone marrow and epithelial cells of the gastrointestinal tract. The spectrum of possible side-effects include: abdominal pain in 75% of women following treatment, conjunctivitis, stomatitis, gastritis, diarrhoea, alopecia (reversible), myelosuppression, liver toxicity, photosensitivity (skin reaction), pneumonitis, renal toxicity and anaphylaxis.

The incidence of side-effects among patients treated with high-dose or multidose methotrexate is reported to be 20–30%. Single-dose regimens, however, currently used for the non-surgical treatment of ectopic pregnancy are associated with minor or no side-effects. Resolution of the adverse effects usually occurs within 72 h after termination of therapy.

Guidelines for the prescription of methotrexate

In order to achieve early identification and prevention of serious side-effects, the Committee on the Safety of Medicines has issued the following guidelines for the prescription of methotrexate.

Myelosuppression

Pretreatment full blood count needs to be documented as a baseline blood count. If an acute decrease in the white cell or platelet count occurs, treatment should be discontinued immediately.

Liver toxicity

Pre-existing abnormal liver function or concurrent abnormal liver function tests should alert medical staff to potential liver toxicity. Again, pretreatment baseline liver function tests are essential.

Renal function

Assessment of renal function is essential prior to treatment because the primary route of excretion of methotrexate is the kidney. Caution should be exercised when there is concurrent medication use with non-steroidal anti-inflammatory drugs as these may adversely affect renal function and further increase serum methotrexate concentrations.

Folinic acid rescue

Methotrexate morbidity can be minimized by the concurrent administration of the 'antidote' folinic acid in the form of calcium folinate which is then converted to 5-methyltetrahydrofolate.

Who will benefit from methotrexate?

The key for successful and safe medical treatment of ectopic pregnancy is proper selection of patients. Methotrexate should be reserved for patients who have an unruptured tubal pregnancy, are clinically asymptomatic and haemodynamically stable. The indications and contraindications for methotrexate therapy are listed below.

Indications

- Initial pretreatment plasma β -hCG concentration below 3000 IU/l.
- Tubal diameter less than 2 cm as defined by direct visualization or ultrasound.
- Absent fetal heartbeat on ultrasound scan.

Contraindications

- Symptomatic patients.
- Haemodynamically unstable patients.
- Presence of haemoperitoneum.
- Initial pretreatment β -hCG concentration greater than 3000 IU/l.
- Tubal diameter more than 2 cm.
- Presence of fetal heartbeat on ultrasound scan.
- Evidence of liver disease, renal insufficiency or myelosuppression.
- Inability of the patient to return for follow-up care.

Although medical management can be successful at serum β -hCG concentrations greater than 3000 IU/l, quality-of-life data suggest that methotrexate should only be used with serum β -hCG concentrations below 3000 IU/l. Shalev et al (1995) reported that following intratubal administration of methotrexate, the failure rate was 24% when the tubal diameter was less than 2 cm and 48% when the diameter was more than 2 cm. The authors recommend that methotrexate should only be used when the size of the ectopic pregnancy is less than 2 cm. Stovall and Ling (1993) found that the administration of methotrexate to patients who had a fetal heartbeat on ultrasound scan was associated with a 14.3% failure rate. In the group of patients without fetal cardiac activity, the failure rate was 4.7%.

Prior to commencing medical treatment, women should be given clear information about the possible need for further treatment and adverse effects following treatment, and they should be able to return easily for assessment at any time during follow-up. Patients should be advised regarding adequate compliance; no use of alcohol, aspirin, non-steroidal inflammatory drugs or folic acid supplements; avoidance of sexual intercourse and sunlight exposure; fluid intake of at least 1.5 l/day; saline mouth washes daily; and delay of pregnancy for at least 3 months after treatment because of the teratogenicity of methotrexate.

Routes of administration and dose

Methotrexate can be administered systemically (intravenously or intramuscularly) or locally using a laparoscopic or transvaginal ultrasound-guided approach. The transvaginal administration of methotrexate under sonographic guidance requires visualization of an ectopic gestational sac, and specific skills and expertise of the clinician. This mode of administration is less invasive and more effective than the laparoscopically 'blind' intratubal injection. Two randomized controlled trials (Fernandez et al 1994, Cohen et al 1996) suggested that local injection of methotrexate was equivalent in effect to systemic methotrexate. The major advantages of direct injection of methotrexate into the tube include smaller dose of the drug, higher tissue concentration and fewer systemic side-effects. In comparison, systemic methotrexate is practical, easier to administer and less dependent on clinical skills. The published literature includes a wide spectrum of protocols for the systemic administration of methotrexate, including:

- standard single dose (60–200 mg IM);
- fixed multiple dose regimen: methotrexate 1 mg/kg body weight IM on days 0, 2, 4, 6 alternated with folinic acid 0.1 mg/kg orally on days 1, 3, 5, 7 followed by 6 days without

- medication. A second course is given on day 14 if the serum hCG concentration on that day is 40% above the initial value on day 0; and
- variable single dose regimen (1 mg/kg or 50 mg/m² of body surface).

The success rate of all three regimens is comparable. Three trials have shown that the administration of methotrexate in a single IM dose of 50 mg/m² body surface area is associated with a complete reabsorption rate of 92%, a subsequent intrauterine pregnancy rate of 58% and a recurrent ectopic pregnancy rate of 9% (Hajenius et al 2007). Reabsorption rate is defined as the time interval between initiation of therapy and undetectable serum hCG concentration. The mean reabsorption time is 30 days, ranging from 5 to 100 days. Tubal patency is reported to be 50–100% (mean 71%) after systemic administration of methotrexate.

Laparoscopic surgery vs methotrexate

O'Shea et al (1994) published the results of a prospective randomized trial comparing intra-amniotic methotrexate with carbon dioxide laser laparoscopic salpingotomy. The salpingotomy group and the local methotrexate group had comparable success rates: 87.5% and 89.7%, respectively. A systematic review showed that systemic methotrexate in a fixed multiple dose IM regimen has a non-significant tendency to higher treatment success than laparoscopic salpingostomy (OR 1.8, 95% CI 0.73–4.6). No significant differences are found in long-term follow-up for intrauterine pregnancy and repeat ectopic pregnancy (Hajenius et al 2007). Methotrexate appears to be effective in a selective group of patients with ectopic pregnancy. Direct and indirect costs of medical therapy are less than half of those associated with laparoscopy. Intramuscular administration eliminates anaesthetic and surgical risks arising from laparoscopic injection of the drug. However, the long-term effect of locally injected pharmacological substances upon the endosalpinx remains largely unknown.

Serum β -hCG levels should be checked 4 and 7 days after the first dose of methotrexate, and a further dose is given if β -hCG levels have failed to fall by more than 15% between days 4 and 7. The level of serum β -hCG is likely to increase between days 1 and 4 after treatment. It has been suggested that although methotrexate is arresting mitosis in the cytotrophoblast, the syncytiotrophoblast may still be able to produce β -hCG. Also, destruction of the cells releases more β -hCG into the systemic circulation. Approximately 15% of women require more than a single dose of methotrexate, and 7% experience tubal rupture during follow-up (Yao and Tulandi 1997, Sowter et al 2001).

It is important to recognize that abdominal pain occurs in 30–50% of patients 6–7 days after the administration of methotrexate. The gynaecologist has to decide if the pain is due to imminent tubal rupture, existing tubal rupture or simply represents postmethotrexate pain. Postmethotrexate pain is localized in the lower abdomen. Its precise aetiology remains largely unknown, but it is likely to be due to a combination of factors, including destruction of the trophoblastic tissue and transtubal haemorrhage leading to peritoneal irritation. Close monitoring of patients is essential in order to avoid unnecessary surgical intervention in the form of laparoscopy or laparotomy. According to Stovall

(1995), regular assessment of haemoglobin is the most useful parameter. The pain usually subsides within 24–48 h and occasionally precedes or follows an episode of vaginal bleeding.

Brown et al (1991) assessed the clinical value of serial transvaginal ultrasonography in the monitoring of ectopic pregnancies treated with methotrexate, and concluded that routine ultrasonography is not necessary after methotrexate treatment. There was no correlation between the pattern of resolution of β -hCG levels and sonographic findings.

Mifepristone and methotrexate

Mifepristone (RU486) has been used in combination with methotrexate for the medical treatment of ectopic pregnancy (Gazvani and Emery 1999). A non-randomized study from France (Perdu et al 1998) only reported one failure in the 30 patients treated with IM methotrexate and oral mifepristone, and 11 failures in 42 patients treated with methotrexate alone. The authors concluded that the combination of mifepristone and methotrexate decreased the risk of failure in medical treatment of ectopic pregnancy. However, further prospective randomized studies are needed to evaluate the role of mifepristone in the medical management of ectopic pregnancy.

Controlled expectant management

When only expectant management was available, it was associated with high morbidity and mortality because the patients who failed expectant management usually presented with significant clinical symptoms, indicating rupture of the ectopic pregnancy. Since then, due to the advancement in ultrasound and rapid access to quantitative β -hCG assays, the nature of expectant management has changed in that it is now controlled and monitored.

Ten prospective studies, with a total of 347 patients managed expectantly, demonstrated that 69% of the ectopic gestations resolved spontaneously. All patients were haemodynamically stable and had decreasing serum β -hCG levels. However, other variables such as size and location of the ectopic pregnancy or presence of fetal cardiac activity were not always specified (Yao and Tulandi 1997). Interventions are required in approximately 23–29% of cases with expectant management (Hahlin et al 1995).

The essential prerequisite for successful expectant management of ectopic gestation is appropriate selection of patients. The Royal College of Obstetricians and Gynaecologists (2004) issued guidelines for the management of tubal pregnancy. The conclusion was that expectant management is more likely to be successful in the following circumstances:

- clinically stable asymptomatic woman;
- baseline serum β -hCG concentrations below 1000–2000 IU/l;
- haemoperitoneum of less than 50–100 ml;
- a tubal mass less than 2 cm; and
- absence of recognizable fetal parts on ultrasound.

Women managed expectantly should be followed twice weekly with serial β -hCG measurements (ideally β -hCG

should be <50% of the initial level within 7 days) and weekly transvaginal ultrasound examination to assess reduction in size of adnexal mass by the end of the first week. Thereafter, weekly β -hCG concentrations and transvaginal ultrasound examination should be undertaken until β -hCG concentrations are less than 20 IU/l. It must be emphasized, however, that tubal rupture has been reported in cases of very low and decreasing serum β -hCG concentration, and expectant management often involves long periods of hospitalization and follow-up. Women should be counselled about the importance of compliance and should be within easy access of medical help.

Anti-D immunoglobulin

All non-sensitized, Rhesus-negative women with suspected or confirmed ectopic pregnancy should receive 250 IU (50 μ g) of anti-D immunoglobulin.

Non-Tubal Ectopic Pregnancy

Cervical pregnancy

A cervical pregnancy is one that implants entirely within the cervical canal. The reported incidence ranges from one in 2500 to one in 18,000 deliveries (0.2% of ectopic pregnancies). Predisposing factors for the development of cervical pregnancy include previous instrumentation of the endocervical canal, previous caesarean delivery, Asherman's syndrome and exposure to DES. Sporadic cases of cervical pregnancy have been reported after controlled ovarian stimulation with human menopausal gonadotrophins and intra-uterine insemination, as well as IVF (Weyerman et al 1989).

Cervical pregnancy produces profuse vaginal bleeding without associated cramping pain. In some cases of advanced pregnancies, it can be associated with urinary symptoms. The clinical and ultrasound criteria for the diagnosis of cervical pregnancy are summarized below (Hofmann et al 1987).

Clinical criteria

The external os is usually dilated and the cervix feels distended or globular with a small uterus on bimanual examination. Curettage of the endometrial cavity reveals no evidence of trophoblastic tissue. The products of conception are confined within the cervix and the internal cervical os is closed.

Ultrasound criteria

No evidence of an intrauterine gestational sac, ballooned cervical canal/barrel-shaped cervix, gestational sac in the endocervix below the uterine arteries, closed internal os and Doppler blood flow around the sac.

The differential diagnoses include an intrauterine pregnancy with a low implantation site (isthmocervical pregnancy), an ongoing spontaneous intrauterine miscarriage, a cervical carcinoma, a cervical or prolapsed submucosal myoma, placenta praevia and trophoblastic tumour.

Early forms of cervical pregnancy are managed conservatively. Conservative treatment includes the use of systemic methotrexate, intra-amniotic feticide, reduction of blood

supply and tamponade. Transvaginal ultrasound-guided local injection of the ectopic pregnancy with methotrexate or potassium chloride has been shown to be successful (Benson and Doubilet 1996). This technique has been used for the treatment of heterotopic coexistent cervical and intra-uterine pregnancy. Similarly, systemic methotrexate alone is 91% efficacious in the treatment of cervical ectopic pregnancy, and a combination of intra-amniotic and systemic methotrexate therapy has been used to increase the chance of successful treatment (Kung and Chang 1999). Currently, there is no recommendation for the optimal dose and route of administration of methotrexate for the treatment of cervical ectopic pregnancy, although gestational age less than 9 weeks, serum β -hCG below 10,000 IU/l, absent fetal cardiac activity and crown-rump length less than 10 mm are associated with a greater chance of success with conservative treatment (Hung et al 1998).

Removal of the products of conception from the cervical canal by suction curettage is likely to stop the haemorrhage. Conservative measures used to arrest bleeding include packing of the uterus and cervix, and insertion of an intra-cervical 30-ml Foley catheter to arrest bleeding, insertion of sutures to ligate the lateral cervical vessels or placement of a cervical cerclage (Kirk et al 2006). In some cases, because of the depth of trophoblastic invasion, major blood vessels are involved and more radical measures such as bilateral uterine artery or internal iliac artery ligation are necessary to control the bleeding. When all the conservative measures have failed to arrest the bleeding, hysterectomy is required. Preoperatively, the patient must be informed about the possibility of hysterectomy and sign the appropriate consent.

Caesarean scar ectopic pregnancy

This is a relatively recent description for ectopic pregnancy location. The incidence is not well known as there are only a few case reports of first trimester caesarean scar ectopic pregnancies described in the literature. Risk factors include previous caesarean section, myomectomy, adenomyosis, IVF, previous dilatation and curettage, and manual removal of the placenta. Clinical presentation can be with either hypovolaemic shock and uterine rupture or painless vaginal bleeding. Ultrasound diagnostic criteria as described by Jurkovic et al (2003) include an empty uterine cavity, a gestational sac located anteriorly at the level of the internal cervical os covering the visible or presumed site of previous lower segment caesarean scar, evidence of functional trophoblastic circulation on Doppler examination, and a negative 'sliding organs sign'. In some cases, hysteroscopy and magnetic resonance imaging have also been used to aid in the diagnosis.

Medical, expectant and surgical methods of management have all been reported. Expectant management does not seem to be an appropriate choice as there is a greater risk of scar rupture and subsequent emergency hysterectomy. As a primary treatment, transvaginal ultrasound-guided local injection of methotrexate (25 mg) in the ectopic gestation has been shown to be associated with a 70–80% success rate (Jurkovic et al 2003). In the presence of fetal cardiac activity, potassium chloride in the ectopic sac followed by local methotrexate has also been shown to be effective (Jurkovic et al 2003). Lastly, there are reports on successful

outcome with the use of systemic methotrexate followed by suction evacuation (Marchiolé et al 2004, Graesslin et al 2005).

Surgical management with suction curettage under ultrasound guidance followed by balloon tamponade is successful in reducing heavy intraoperative bleeding. Uterine artery embolization can also be used as an adjunctive therapy to reduce bleeding. An alternative approach can be the use of a Shirodkar suture prior to suction evacuation, with approximately 79% of cases requiring the suture to be tied to reduce bleeding (Jurkovic et al 2007). Finally, in cases presenting with hypovolaemic shock, laparotomy followed by hysterectomy is the only option available.

Ovarian pregnancy

Ovarian pregnancy represents the most common type of non-tubal ectopic pregnancy and occurs in 0.2–1% of all ectopic pregnancies. The incidence ranges from one in 40,000 to one in 7000 deliveries. Ovarian pregnancy has been reported after IVF treatment (Marcus and Brinsden 1993) and clomifene citrate ovulation induction (De Muylder et al 1994). The only risk factor associated with the development of an ovarian pregnancy is the current use of an IUCD.

The symptoms and signs of an ovarian pregnancy are similar to those of tubal pregnancy. Usually, the diagnosis is made during a laparoscopy or laparotomy. The classic criteria of Spiegelberg (1878) for the diagnosis of an ovarian pregnancy are as follows:

- the gestational sac must occupy a portion of the ovary;
- the gestational sac must be connected to the uterus by the ovarian ligament;
- ovarian tissue must be identified in the wall of the sac; and
- the fallopian tube on the affected side of the pelvis must be intact.

Transvaginal ultrasound can help in the diagnosis of an ovarian pregnancy which usually appears on or within the ovary as a cyst with a wide outer echogenic ring. A yolk sac or an embryo is rarely seen and the appearances usually lag in comparison with the gestational age (Comstock et al 2005). These are usually mistaken for corpus luteal cysts. 3D-ultrasound imaging has been shown to be useful in differentiating a corpus luteum from an ovarian pregnancy (Ghi et al 2007), whereas Doppler ultrasound is not very helpful in differentiating between them. Differential diagnoses include tubal pregnancy or complications of an ovarian cyst.

Treatment consists of resection of the trophoblast from the ovary and preserving as much ovarian tissue as possible. Salpingo-oophorectomy is rarely necessary. Persistent trophoblast can be treated with systemic methotrexate. Systemic methotrexate as a primary treatment has also been used successfully.

Abdominal pregnancy

There are two types of abdominal pregnancy:

- primary peritoneal implantation of the blastocyst; and

- secondary peritoneal implantation of the conceptus following tubal miscarriage or rupture, or less often, after uterine rupture with subsequent implantation within the abdomen.

Secondary abdominal pregnancies are far more common. Abdominal pregnancy represents approximately 1.4% of all ectopic pregnancies, and its incidence varies from one in 3000 to one in 10,000 deliveries. Abdominal pregnancies are associated with high maternal (0.5–1.8%) and perinatal mortality (40–95%) (Atrash et al 1987). The incidence of congenital fetal abnormalities ranges from 35% to 75%. Most of the abnormalities are caused by growth restriction and external pressure on the fetus. Common fetal problems include pulmonary hypoplasia, facial asymmetry and talipes.

The classic criteria for the diagnosis of primary abdominal pregnancy are:

- no evidence of uteroplacental fistula;
- presence of normal tubes and ovaries with no evidence of a recent or past pregnancy; and
- pregnancy only attached to the peritoneal surface.

The diagnosis of an abdominal pregnancy must be made early enough to eliminate the possibility of secondary implantation after primary tubal nidation. In the first and early second trimesters, the symptoms may be the same as those of a tubal ectopic gestation. As the pregnancy advances, however, unexplained abdominal pain, occasional vomiting, diarrhoea or constipation may occur. Fetal movements are very marked or painful and felt high in the abdomen. Braxton-Hicks contractions are absent. Abdominal palpation may disclose persistently abnormal fetal lie, abdominal tenderness and easy palpation of the fetal parts. The fetus gives the impression that it lies just under the skin of the abdomen. On bimanual examination, the uterus is usually normal in size and the cervix is long, firm and displaced. Abdominal ultrasound provides an unequivocal diagnosis, although computed tomography and magnetic resonance imaging have also been used to confirm the diagnosis.

The treatment is laparotomy as soon as the diagnosis is made. This is not to be undertaken lightly. The objectives are to remove the fetus and to ligate the umbilical cord close to the placenta without disturbing it. The placenta is allowed to be absorbed; if left alone, it rarely presents problems of bleeding or infection. The placenta should only be removed when the surgeon is absolutely certain that total haemostasis can be achieved. Removal of the placenta is possible if it is attached to the ovary, the broad ligament and the posterior surface of the uterus. Attempts to remove the placenta from other intra-abdominal organs are likely to cause massive haemorrhage due to the invasive properties of the trophoblast and the lack of cleavage planes. Adjuvant treatment with methotrexate along with selective arterial embolization has been recommended to stem the haemorrhage (Oki et al 2008). Placental involution can be monitored using serial ultrasonography and β -hCG concentrations. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation, haemorrhage and peritonitis. The literature reports on successful management of abdominal pregnancies laparoscopically and with systemic methotrexate (Shaw et al 2007).

Interstitial pregnancy

In interstitial pregnancy, the zygote/blastocyst implants in the portion of the uterine fallopian tube that traverses the uterine wall. It occurs in one in 2500 to one in 5000 live births and comprises 2% of all ectopic pregnancies. Pre-disposing factors are similar to those of other tubal pregnancies.

The implantation site may be in the utero interstitial (inner segment), the true interstitial (middle segment) or the tubo interstitial (outer segment) region. The duration of pregnancy depends on its location. Implantation in either the inner or outer segments results in early rupture. Implantation in the middle segment involves a greater mass of myometrium and permits the pregnancy to advance to a somewhat later date. Rupture of the uterine wall is the most frequent outcome and the haemorrhage is usually severe. The signs and symptoms are similar to those of tubal ectopic pregnancy. Intermittent recurrent, sharp abdominal pain occurs at 4–6 weeks. Sudden severe abdominal pain is followed by collapse. Ultrasound diagnosis is made by visualization of the interstitial line adjoining the gestational sac and the lateral aspect of the uterine cavity, and continuation of the myometrial mantle around the ectopic sac (Jurkovic and Mavrellos 2007). Interstitial pregnancy must be differentiated from cornual myoma, pregnancy in one horn of a bicornuate uterus and a large endometrioma at the uterotubal junction.

Laparoscopy will reveal an asymmetrical enlargement of the uterus, displacement of the uterine fundus to the opposite side, elevation of the involved cornu, and rotation of the uterus on its long axis. The round ligament may be lateral to the gestational sac. Traditionally, interstitial pregnancies have been managed by laparotomy followed by wedge resection or hysterectomy. Since the 1990s, laparoscopic cornual resection and salpingotomy have become the surgical treatment of choice (Tulandi et al 1995). Laparoscopic vasopressin injection followed by excision of the pregnancy and endoloop closure or laparoscopic suturing for haemostasis has also been described.

In the presence of haemorrhagic shock, immediate laparotomy is required. In these cases, simple wedge resection, reconstruction of the uterine wall and salpingectomy will be necessary. In some cases with a severely damaged uterine wall, the only way to control haemorrhage is to perform a total abdominal hysterectomy and unilateral salpingo-oophorectomy. Cornual resection and uterine reconstruction has been associated with uterine rupture in pregnancy or during labour in subsequent gestations.

Intraligamentous pregnancy

Intraligamentous pregnancy is another rare form of non-tubal pregnancy that occurs in approximately one in 300 ectopic pregnancies. It is commonly secondary to penetration of the tubal wall by trophoblastic tissue and advancement of the trophoblast between the two layers of the broad ligament. Clinical findings are similar to those of abdominal pregnancy. The uterus is felt separately and is usually dis-

placed to the opposite side. If the pregnancy persists, the mass may become palpable abdominally. The diagnosis is usually made at the time of surgery. The surgical principles are similar to those applied to abdominal pregnancy. Problems of extensive placental invasion of nearby structures are less likely. If possible, the placenta should be removed; when this is not possible, it can be left *in situ* and allowed to resolve.

Cornual pregnancy

The term 'cornual pregnancy' indicates that the pregnancy has occurred in one horn of a bicornuate uterus or in the rudimentary horn of a unicornuate uterus. It is very rare (one in 100,000 pregnancies) but carries a 5% maternal mortality. Asymmetrical enlargement of the early pregnant uterus should suggest a uterine anomaly. Unusual discomfort and tenderness may be described. Ultrasound criteria for diagnosis include a single interstitial part of the fallopian tube in the main uterine body, a gestational sac which is mobile and separate from the uterus, surrounded by myometrium and a vascular pedicle adjoining the gestational sac to the unicornuate uterus (Jurkovic and Mavrellos 2007).

Conservative, laparoscopic and open surgical methods of management have all been described. If the diagnosis is made earlier in pregnancy, treatment is excision of the rudimentary horn and the tube on the affected side. Congenital abnormalities of the Müllerian duct are associated with renal anomalies; therefore, renal tract imaging should be ordered postoperatively.

Heterotopic pregnancy

Heterotopic pregnancy is defined as the simultaneous occurrence of an intrauterine and an extrauterine pregnancy. In spontaneous conception, the incidence has traditionally been quoted as one in 30,000 pregnancies. However, the incidence has risen to one in 3889 pregnancies due to the increased incidence of genital infections and the use of ovulation induction agents. With assisted conception techniques, particularly IVF and embryo transfer, 1–3% of all clinical pregnancies are heterotopic; therefore, it is imperative to visualize adnexae at the time of ultrasound scan for fetal viability (Svare et al 1993).

Unusual abdominal pain in the presence of spontaneous miscarriage or profuse uterine bleeding with signs of peritoneal irritation should suggest a heterotopic pregnancy. Serial measurements of serum β -hCG concentration are not helpful. The diagnosis depends on maintaining a high index of suspicion, particularly for patients in the high-risk group, and by transvaginal ultrasound scan or laparoscopy. If the diagnosis is established at an early stage, the prognosis of the intrauterine pregnancy is more favourable. Depending upon the size and viability of the ectopic pregnancy, treatment can be conservative with local intra-amniotic injection of methotrexate in the ectopic gestation or surgery. After a surgical procedure, the intrauterine pregnancy continues in approximately 75% of patients.

KEY POINTS

1. Ectopic pregnancy is a pregnancy that is implanted outside the uterine cavity. The ampullary segment of the fallopian tube is the most common site of ectopic pregnancy.
2. Independent risk factors consistently shown to increase the risk of tubal pregnancy include previous tubal pregnancy, previous laparoscopically proven PID, previous tubal surgery and current IUCD users.
3. Ectopic pregnancy should be considered as an important differential diagnosis in any woman of reproductive age who presents with the triad of abdominal pain, irregular vaginal bleeding and amenorrhoea. The presentation of symptomatic patients with a tubal ectopic pregnancy can be acute or subacute.
4. The introduction of highly sensitive biochemical assays for the measurement of β -hCG concentration and transvaginal sonography have made early diagnosis of ectopic pregnancy possible.
5. PUL has been used as a diagnosis in women with a positive pregnancy test and no signs of intrauterine or extrauterine pregnancy or retained products of conception on an initial transvaginal ultrasound scan. PULs are primarily managed conservatively with serum β -hCG levels/ratios and serial transvaginal ultrasound scans.
6. Laparoscopic surgery is the treatment of choice for most tubal pregnancies and is superior to laparotomy. Following salpingectomy, the subsequent intrauterine pregnancy rate is 50% and the recurrent ectopic pregnancy rate is 10%. Following salpingotomy or salpingostomy, the subsequent intrauterine pregnancy rate is 53% and the recurrent ectopic pregnancy rate is 14%.
7. Administration of methotrexate allows non-invasive outpatient management of tubal pregnancy. Methotrexate should be considered when the initial pretreatment β -hCG concentration is less than 3000 IU/l, the tubal diameter is less than 2 cm, there is no evidence of fetal heartbeat on ultrasound scan, and the patient is haemodynamically stable and asymptomatic.
8. Expectant management of tubal ectopic pregnancy is more likely to be successful if the initial β -hCG concentration is less than 1000 IU/l, the diameter of the tubal mass is less than 2 cm, the fetal pole is absent on ultrasound scan, and the patient is asymptomatic.
9. Non-tubal ectopic pregnancies are rare. However, recently, the incidence of heterotopic pregnancy has increased significantly following assisted reproduction techniques.

HOW USEFUL ARE ENDOCRINE TESTS?	384	KEY POINTS	389
THERAPY FOR HIRSUTES	386		

Introduction

Hair follicles are stimulated by androgens to either enlarge on the face and body or to shrink on the vertex of the scalp. These changes occur in the female after puberty and probably develop to a small extent in all women. A small number of women develop excessive changes in hair, prompting advice from beauty therapists or physicians. The heaviness of facial or body hair growth that is necessary for a woman to consider herself to be hirsute is dependent on racial, cultural, social and economic factors. Although the pattern of hair growth is similar in all races, there is a variation in the heaviness of growth between ethnic groups. Furthermore, Shah (1957) in India and Lunde and Grottum (1984) in Norway have both stressed that women are more likely to consider themselves to be hirsute if they have significant growth on the upper lip, chin, chest and upper back.

The problem with defining hirsutism is that all measurements are subjective (Barth 1997). Large studies of unselected women in the USA (DeUgarte et al 2006) and Scandinavia (Lunde and Grottum 1984) have shown that it is impossible to separate hirsute from non-hirsute women on the basis of hair scoring scales, as women with similar hair scores may or may not consider that they have excessive hair growth. The problem with physician scales is that they do not consider the effect of hair localization. Is a woman with facial hair but no body and limb hair more or less hirsute than a woman with a hairless face but a hairy trunk and limbs?

The standard scoring scale designed by Ferriman and Gallwey (1961) (Figure 26.1) defined 1.2% of females as hirsute, but this was based purely on mathematical grounds (i.e. 2 standard deviations from the mean). This contrasts with women's perspectives. A study of 400 unselected students, 60% of whom were Welsh, showed that 9% consid-

ered themselves to be disfigured by their facial hair growth (McKnight 1964). A study of unselected women in the USA found that approximately 20% of women had modified Ferriman and Gallwey scores greater than 3, and of these women, 70% considered themselves to have excessive facial and body hair. Furthermore, women with hirsutism give their hair growth a higher score than their physicians (Kozloviene et al 2005).

The subjectivity in the concept of hirsuties can be simplified by accepting that any woman who complains of excessive hair is hirsute. It then follows that the physician's role is to determine whether invasive investigations (see below) are required, and what sort of therapy is most appropriate for the degree of hair growth.

Hirsuties or hypertrichosis?

Hirsutism is a purely clinical diagnosis which is based on the growth and pattern of hair on the face and body of women. The pattern of hair growth in hirsute women is assumed to follow a similar pattern to that which develops on males after puberty. Hair first appears on the upper lip, followed by the chin and cheeks, and then the lower legs, thighs, forearms, abdomen, buttocks, chest, back, upper arms and shoulders. The hair shafts themselves are coarse, curly and tend to rise above the skin surface, rather than lying flush with the skin as in hypertrichosis.

Hypertrichosis needs to be differentiated as it is not androgen mediated and therefore does not respond to antiandrogen therapy. The onset of hair growth is not related to puberty; there is no hair growth pattern but there is a uniform diffuse growth of hair over the body. The individual hair shafts tend to be finer and lie flat against the skin, rather than being coarse, curly and rising above the skin surface. Hypertrichosis may be congenital or acquired due to drug therapy and some metabolic disorders (Table 26.1).

Figure 26.1 The hirsuties scoring scale designed by Ferriman and Gallwey. The body is divided into 11 zones as illustrated, and each zone is scored 0–4 giving a maximum score of 44. Ferriman and Gallwey excluded the lower arm and leg, and defined hirsuties as a score of >8. Unfortunately, there is considerable interobserver variation in scoring, so all investigators need to standardize their individual score rates.

Table 26.1 Aetiology of hirsuties and hypertrichosis

Causes of hirsutism	Causes of hypertrichosis
Ovarian, e.g. polycystic ovary syndrome, ovarian tumours Adrenal, e.g. congenital adrenal hyperplasia, adrenal tumours Cushing's syndrome Gonadal dysgenesis Androgen therapy Valproate therapy for epilepsy Obesity (due to consequent PCO) Prolactinoma (due to consequent PCO) Stress Idiopathic	Drug therapy, e.g. cyclosporin, diazoxide, minoxidil, penicillamine etc. Congenital disorders, e.g. hypertrichosis lanuginosa and other syndromes often associated with mental retardation Acquired hypertrichosis lanuginosa as a paramalignant condition Metabolic disorders, e.g. lipodystrophy, mucopolysaccharidoses, malnutrition

PCO, polycystic ovaries.

Investigation

A diagnosis of hirsutism is based purely on the patient's history and clinical examination. The purpose of investigation is to determine if there is any significant underlying condition which will influence further management. The majority of patients will have underlying polycystic ovary syndrome, and any investigative strategy should be designed to select those subjects who have a significant endocrinopathy that requires specific therapy.

Diagnostic approach to the hirsute woman

The history of the duration and severity of hirsutism is helpful if there is suspicion of a serious underlying cause:

- longstanding mild hirsutism with regular cycles and no features of systemic virilization; these women require no further investigation;
- longstanding moderate hirsuties with or without menstrual cycle disturbances. Most of these patients will have polycystic ovaries. Further investigation is only required if serum testosterone is elevated or if the patient seeks therapy for another symptom related to hyperandrogenism, such as infertility; and
- recent-onset hirsuties and virilization, or very severe hirsuties with a long history. Features of systemic virilism include: clitoromegaly, deepening of the voice, recent-onset temporal balding, increasing muscle bulk and decrease in breast size. These women require a comprehensive endocrine evaluation for an androgen-secreting tumour (Figure 26.2).

What is the evidence for this approach?

There have been two large studies to support this approach. Both confirmed the very low prevalence of serious endocrine disease, and it is clear that with the evidence of clinical case histories, these conditions are largely apparent on history and clinical examination.

Moran et al (1994) reported on 250 premenopausal (<38 years) women presenting with various symptoms who were noted to be hirsute. Ninety-six percent were diagnosed with polycystic ovaries, idiopathic hirsuties or obesity; 2% were diagnosed with congenital adrenal hyperplasia (CAH); and 1.6% were either iatrogenic (one case) or due to an ovarian tumour (two cases) or Cushing's syndrome (one case).

O'Driscoll et al (1994) reported a series of 350 consecutive patients who had presented with either hirsuties or androgenic alopecia. They identified eight women from this series with clear endocrine diseases; two had pituitary tumours (prolactinoma and acromegaly). The others were identified by a grossly elevated serum testosterone (>5 nmol/l). In total, 13 women had elevated testosterone; six had polycystic ovaries, two had late-onset CAH, one had virilizing CAH that had been ignored in childhood, one had an adrenal carcinoma, one had a postmenopausal Leydig cell tumour, one had corticosteroid 11-reductase deficiency, and the diagnosis in one hyperandrogenized postmenopausal woman was not elucidated. On the basis of the clinical details given in the report, only two diagnoses of late-onset CAH would have been missed by clinical evaluation alone (one had regular cycles and two children, the other had a long history of oligomenorrhoea; both had polycystic ovaries on ultrasound examination).

Arguably, the most important purpose for investigation is to identify those women with androgen-secreting tumours, since they require different therapy. Derksen et al (1994) reported a series of two adrenal adenomas and 12 carcinomas in which hirsutism was the presenting symptom. The women with adenomas were described as being severely virilized. Six of the women with carcinoma had clinical signs of Cushing's syndrome; of the remaining six cases, four were

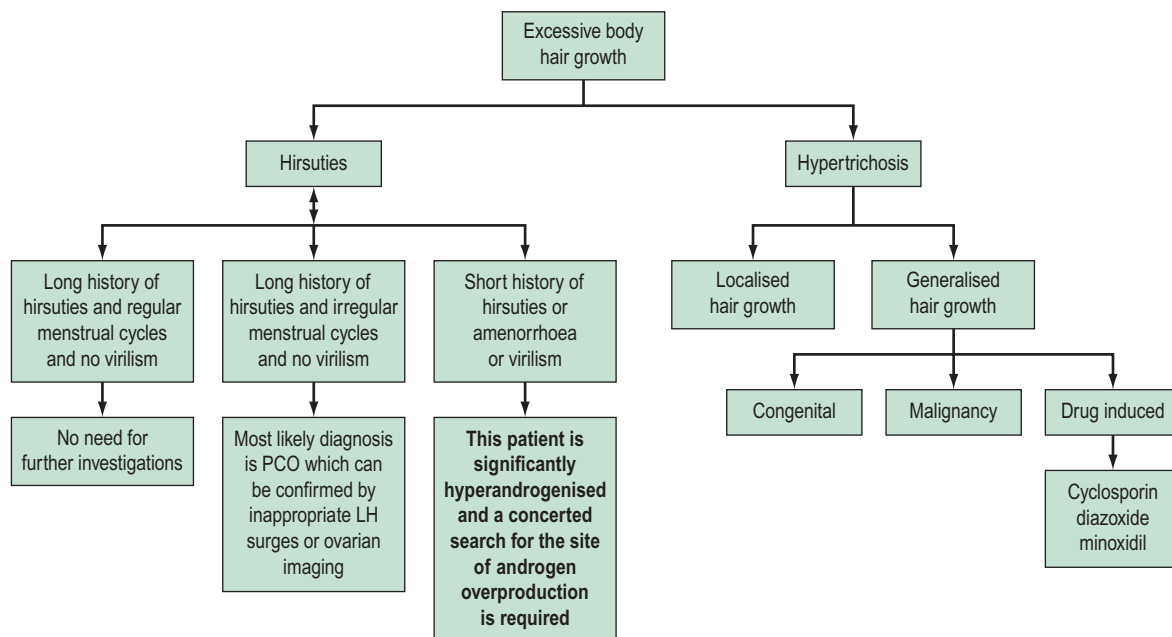

Figure 26.2 Diagnostic approach for a woman complaining of excess facial and/or body hair. PCO, polycystic ovaries; LH, luteinizing hormone.

severely virilized and the other two women presented with abdominal pain.

Functioning ovarian tumours which secrete androgens and therefore cause virilization are rare and represent only 1% of all ovarian tumours. In these cases, hirsuties is a nearly universal feature. Amenorrhoea develops rapidly in all premenopausal patients, and systemic virilization with alopecia, cliteromegaly, deepening of the voice and a male habitus develops in approximately half of patients. Meldrum and Abraham (1979) reviewed the literature of 43 women with virilizing ovarian tumours; seven had a serum testosterone level below 7.0 nmol/l but all were clinically virilized, and one 65-year-old woman was reported as not virilized but her serum testosterone level was more than 12 nmol/l.

In conclusion, the vast majority of hirsute women have polycystic ovaries, and those women with androgen-secreting tumours can be identified by clinical evaluation and a single serum testosterone estimation (Figure 26.3).

How Useful Are Endocrine Tests?

The laboratory findings in reports of hirsute women demonstrate considerable heterogeneity. This may be due to differences in diagnostic criteria for the studies; for example, hyperandrogenaemia, acne and/or hirsutism, or women with polycystic ovaries/menstrual disturbances. A further factor may be the degree of hair growth necessary to define whether a woman is considered to be hirsute (Barth et al 2007). A third point has been proposed by Toscano et al (1983) who suggested that the endocrine abnormalities are dependent on the length of the history of hirsutism. They posed the question 'is hirsutism an evolving syndrome?', and whilst their interpretation of the findings may be argued, it is clear that (i) a degree of hirsutism and/or oligomenorrhoea is necessary before hormonal abnormalities may be

present, and (ii) not all hirsute women have abnormal circulating hormones.

Investigations to diagnose polycystic ovaries

A diagnosis of polycystic ovaries was originally made on the basis of clinical signs and gross anatomical features of the ovaries; indeed, the majority of cases can be diagnosed on the basis of hirsuties and oligo-/amenorrhoea. Confirmation of the clinical diagnosis is made variably by ultrasound imaging or endocrine tests. The choice of test is largely philosophical; imaging makes a diagnosis that matches the anatomical description of the condition, whereas endocrine tests can, at best, only act as surrogates.

Ovarian imaging compares extremely favourably with anatomical appearance in those subjects who have had abdominal laparoscopy, whereas the use of gonadotrophins is less well established as a diagnostic tool. Approximately 50% of women with polycystic ovaries have an elevated concentration of luteinizing hormone (LH), and 40% of women with elevated LH have polycystic ovaries. The use of gonadotrophins is further complicated by assay methodology. In view of these factors, the latest guidelines to diagnose polycystic ovaries have abandoned their use (Rotterdam ESHRE/ASRM-sponsored PCOS Consensus Workshop Group 2004). The over-riding problem is that approximately 10% of women with ultrasound-diagnosed polycystic ovaries will have normal endocrine tests, however many are performed. This may be due to the relationship between body weight and the dynamics of testosterone production (Figure 26.4).

Most recommendations suggest a battery of androgen tests, but this is probably still based on the unreliability of testosterone assays (Rosner et al 2007). This should become less of a problem as measurement by tandem mass spectrometry becomes more routine. A single testosterone meas-

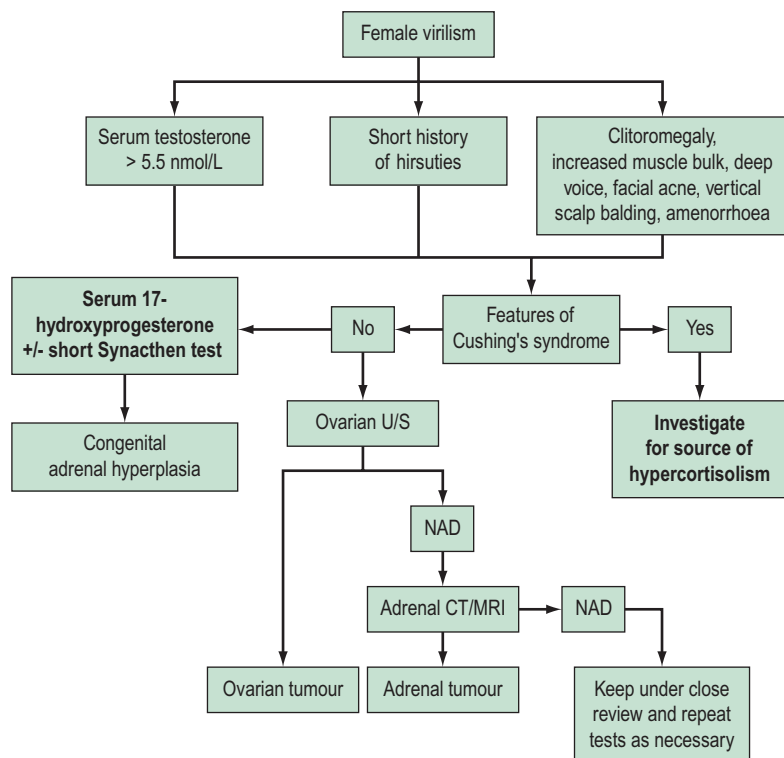

Figure 26.3 Diagnostic approach for a woman with features of systemic virilism. U/S, ultrasound; CT, computed tomography; MRI, magnetic resonance imaging; NAD, no abnormalities detected.

urement taken in the morning during the early follicular phase measured with a reliable assay is probably all that is required in the first instance (Martin et al 2008).

Short Synacthen test for late-onset congenital adrenal hyperplasia

The incidence of late-onset CAH in women with hirsutism is variously reported at 1–12% depending on the source of patient referral. Short Synacthen testing has been used extensively as a research tool, but its use in routine practice cannot be recommended. Firstly, there is no sharp cut-off value of 17-hydroxyprogesterone following Synacthen that can be used to define late-onset CAH. Secondly, treatment for hirsute women with late-onset CAH should not be influenced by the diagnosis since antiandrogen therapy with cyproterone acetate (CPA) is more effective than corticosteroids (Spritzer et al 1990). Moreover, corticosteroids aggravate insulin resistance and, theoretically, worsen the hyperandrogenism. Finally, there does not appear to be a need to identify women with late-onset CAH since they do not seem to need protection against stress-related corticosteroid deficiency.

Evaluation of metabolic factors

Polycystic ovary syndrome is now recognized to be a systemic disorder underpinned by insulin resistance. Insulin plays a key role as an amplifier of gonadotrophin-stimulated ovarian androgen production, and also as a growth factor for hair follicle. The effects of hyperinsulinaemia include android obesity, glucose intolerance, hyperlipidaemia and possibly impaired fibrinolysis. The lipid profiles show the pattern associated with patients who have ischaemic heart

Figure 26.4 Although serum testosterone is usually reported as slightly elevated in women with polycystic ovaries (PCO) or hirsuties, it can be seen from this redrawing of the original data of Bardin and Lipsett (1967) that testosterone production rates are closely related to body mass irrespective of the patient's phenotype. IH, idiopathic hirsuties.

Data redrawn from Thomas PK, Ferriman DG. Variation in facial and pubic hair growth in white women. *Am J Phys Anthropol.* 1957 Jun;15(2):171–180, Wiley.

disease, namely raised triglycerides and low high-density-lipoprotein cholesterol, and hirsute women undergoing coronary angiography have more pronounced arterial disease than non-hirsute women (Wild et al 1990). Moreover, long-term studies of women with polycystic ovaries have shown an increase in diabetes and hypertension, and the central obesity phenotype in women carries an increased risk of

cardiovascular disease (see Chapter 18, Polycystic ovary syndrome, for more information).

These metabolic factors are already well established during adolescence, as evidenced by the changes in bony structure. These must have been completed by the time of epiphyseal fusion at the end of the second decade. This was clearly demonstrated by Ferriman et al (1957) who noted that hirsute women had increased shoulder width and reduced bi-iliac width compared with non-hirsute women, and that these differences were greater in those women who noted that their hirsutism began during adolescence.

Recommendations for the investigation of hirsute women

Most women with hirsuties are either seeking reassurance that they are not changing sex or are seeking advice regarding therapy for their hair. Measurement of a single serum testosterone during the early follicular phase may be a useful therapy for the former, and is a useful first-line indicator of a serious endocrine disease, although, as discussed above, women with the latter will be identified by history and clinical examination. There seems to be no benefit to be gained by extensive endocrine tests in uncomplicated cases of hirsutism, since the decision to treat is not based on endocrine test results.

Since there are serious adverse metabolic factors in both lean and obese women with polycystic ovaries, it would be prudent to screen for impaired glucose tolerance by a fasting glucose and to measure a fasting plasma lipid profile.

Postmenopausal women

A different strategy is required for postmenopausal women because, unlike younger women, they cannot be stratified on the basis of menstrual pattern. However, as women age, the pattern of facial and body hair changes (Figure 26.5); hair on the face increases whilst it involutes elsewhere. Hair growth on the chest, shoulders and upper back can be considered indications for further investigation. Hormonal changes in hirsute postmenopausal women are minor with small increases in testosterone compared with appropriate controls, so an elevated testosterone more than twice the upper limit of age-related normal or approximately 3.0 nmol/l should also be considered as a trigger for further investigation. Postmenopausal women with unexplained hirsuties have normal lipids, but women with ovarian hyperthecosis should be investigated further since they appear to have a very high incidence of glucose intolerance and vascular disease (Barth et al 1997).

Therapy for Hirsuties

Most women will be satisfied with the reassurance that they are not 'turning into men' and may not require any further medical attention. Some may need advice about local destructive methods and some may need to be advised how to use those methods. The vast majority of women have experience in at least one form of depilation (Toerien and Wilkinson 2005), so many women will be seeking medical help because they have already found these methods wanting. It is important to accept that the choice of therapies

Figure 26.5 Differences in facial and abdominal hair in women aged 15–85 years. Data were collected on 584 women admitted to hospital. Hair was graded 0–4 at each site, and scores of 3 or 4 were considered to represent significant hair growth for this graph.

Redrawn from Bardin CW, Lipsett MB, Testosterone and Androstenedione Blood Production Rates in Normal Women and Women with Idiopathic Hirsutism or Polycystic Ovaries, *Journal of Clinical Investigation*, 1967; 46: 891–902.

will depend on the needs and desires of the patient, and not the degree of hirsutism.

Psychological factors

There is a societal expectation in Western culture for women to be hairless, and hairiness in women is overwhelmingly constructed in a negative fashion. Is it surprising, therefore, that women regard their excess hair growth with unhappiness? They spend considerable amounts of time managing their facial hair and have high levels of emotional stress, depression and anxiety. Most concerning is their poor performance in social arenas and in relationships (Lipton et al 2006), leading to an overall poor quality of life (Barnard et al 2007). Some of the symptomatology can be explained by comorbidities such as obesity and acne (Barth et al 1993), which reinforces the need to treat holistically and to provide time and sympathy rather than considering hirsuties as a purely medical condition. In the author's experience, only one-third of women want internal medical therapy after receiving a full explanation of their condition and informed advice about topical therapies.

Topical/cosmetic procedures

Hair bleaching with hydrogen peroxide and hair plucking are both useful and will have been used by most women prior to seeking medical help. Depilatory creams reduce the strength of the hair fibre by reducing the chemical sulphur-sulphur bonds which can then be sheared apart by rubbing the skin. Unfortunately, prolonged application, necessary for thick hairs, has the same effect on the stratum corneum and leads to redness and soreness. Shaving may be the only treatment that produces an acceptable cosmetic effect. This should be discouraged as no therapy can be as effective, and electrologists need a short stubble to direct their needles.

There is no evidence that shaving has any effect on hair growth despite popular belief (Peereboom-Wynia 1972).

Plucking hairs out over large areas is performed by waxing. This is a painful method and is often complicated by folliculitis since the wax oils penetrate the potential space within the outer root sheath where they establish an inflammatory reaction. This can be avoided by the use of natural sugars as a wax substitute which are not so irritant to the hair follicle; this technique is widely used in the Middle East.

Weight reduction

Holistic lifestyle changes must be considered as a primary aim in all women with polycystic ovary syndrome and hirsuties for all the reasons of cardiovascular risk outlined above and also to reduce the risk of developing diabetes. Unfortunately, weight loss is difficult to achieve in many subjects despite the beneficial effects on all the risk factors viz. lipids, insulin resistance and blood pressure. Some subjects may benefit from treatment with weight-loss medication such as orlistat and sibutramine. There is only anecdotal evidence of the benefit of weight reduction on hair growth using holistic measures. Metformin, despite its ability to improve cardio-metabolic status, does not improve hirsuties unless there is weight loss and cannot be recommended (Cosma et al 2008). Weight loss following bariatric surgery does, however, result in significant reduction in hair growth (Ecobar-Morreale et al 2005).

Electrolysis

Electrolysis is a popular procedure used for permanent hair removal. It involves the insertion of a small needle or probe into the hair follicle through which an electric current is delivered. This causes tissue damage and destruction of the hair follicle, and results in a microscar surrounding the follicle which is barely perceptible at the skin surface. Focal erythema and oedema following treatment usually resolve within a few hours.

Electrolysis is more effective on anagen hairs; therefore, shaving a few days before electrolysis greatly increases its efficacy because it ensures that only growing anagen hairs are epilated. This is particularly important during the initial treatment of an area because as many as 60% of the hairs may be in telogen, which are difficult to eradicate permanently. The cosmetic outcome of electrolysis is extremely dependent on the skill of the operator, and patients should be advised to only accept therapy from appropriately trained personnel. Multiple treatment sessions are necessary due to the practice of avoiding simultaneous treatment of adjacent hair follicles (within 3–4 mm of each other) in order to reduce unnecessary thermal skin injury.

Complications are quite unusual in skilled hands but patients who are prone to hypertrophic scarring, keloids, postinflammatory hyperpigmentation or other cutaneous dyschromias should be advised that these complications may result from electrolysis treatment.

Laser depilation

Lasers cause damage to the hair follicle by irradiating the skin with high energy light. This is absorbed by melanin in

the hair bulb which, in turn, suffers thermal injury as the energy is dissipated. This mechanism is fine for subjects with dark hair and light skin. Subjects with dark skin who have considerable quantities of melanin in the epidermis will suffer burns. Similarly, those subjects who burn easily in sunlight will be unable to tolerate laser therapy. However, despite these limitations, laser therapy is widely used across the globe for epilation.

Although laser therapy is routinely advertised as producing permanent hair removal, there is a lack of long-term studies. In fact, only short-term studies (≤ 6 months) have been performed. Moreover, there have been no formal comparisons against electrolysis to determine which gives the best long-term results. Adverse effects include blistering, hyperpigmentation, scabbing, hypopigmentation, scar formation and thrombophlebitis.

Systemic Antiandrogen Therapy

It is important that hirsute women are carefully selected prior to initiating therapy for the following reasons. Firstly, the effect on hair growth takes several months to become apparent and only partial improvements may be expected. Secondly, antiandrogens will potentially feminize a male fetus and it is essential that treated women do not become pregnant. Thirdly, these drugs only reduce hair scores by 25–33% and they have a suppressive effect rather than a curative effect; this wears off a few months after cessation of therapy. In view of this, therapy may need to be taken indefinitely if a favourable improvement occurs. Finally, the long-term safety of these drugs is unknown, and tumours in laboratory animals have been reported with several of the following agents.

The coexistence of obesity in many hirsute women has been discussed above. Women who are overweight should be advised to reduce their weight since a reduction as small as 5% has been shown to be associated with both a regulation in menses and a reduction in hair growth. However, once a decision has been made to treat an hirsute woman, weight does not seem to play an important role in the efficacy of treatment (Crosby and Rittmaster 1991). Weight may be an important factor in the presentation of women with hirsuties, and should be considered in the treatment possibilities since weight gain or difficulty in weight loss is experienced with oral contraceptive therapy.

Oral contraceptive agents

Cyproterone acetate

CPA is both an antiandrogen and an inhibitor of gonadotrophin secretion. It reduces androgen production, increases the metabolic clearance of testosterone and binds to androgen receptors; in addition, long-term therapy is associated with a reduction in the activity of cutaneous 5 α -reductase. CPA is a potent progestogen but does not reliably inhibit ovulation and is usually administered with cyclical oestrogens in order to maintain regular menstruation and to prevent conception since there is a risk of feminization of a male fetus.

CPA is administered either as the Dianette pill alone taken for 21 days, or with supplementary CPA 50–100 mg taken

for the first 10 days (the reverse sequential regimen of Hammerstein). This regimen was designed to allow for CPA stores to be cleared from adipose tissue by the end of the cycle to allow menstruation. Other regimens have been designed using intramuscular oestrogens and/or CPA.

Current dosage recommendations for CPA usually advise that 50 or 100 mg CPA should be administered for 10 days/cycle. However, three dose-ranging studies have suggested that there is no dose effect (Molinatti et al 1983, Belisle and Love 1986, Barth et al 1991).

Side-effects of CPA include weight gain, fatigue, loss of libido, mastodynia, nausea, headaches and depression. All these side-effects are more frequent with a higher dose. Contraindications to its use are the same as for the contraceptive pill and include cigarette smoking, age, obesity and hypertension. All patients should have their liver function monitored in view of the rare occurrence of liver damage.

Desogestrel (Marvelon)

Desogestrel is the progestogen used in the Marvelon contraceptive pill which contains 30 µg ethinyl oestradiol and 150 mg desogestrel. There have been few studies of its efficacy in hirsuties. All have reported subjective and/or objective reductions in hair growth of 20–25% after 6–9 months of therapy, with a high degree of patient satisfaction.

Drisperonone

Drisperonone is a novel progestogen with antiandrogenic action. It appears to help acne, and the only randomized study suggests that it is as good as Dianette (Batukan et al 2007).

Antiandrogenic compounds

Spironolactone

Spironolactone has several antiandrogenic pharmacological properties. It reduces the bioavailability of testosterone by interfering with its production and increasing its metabolic clearance. It binds to the androgen receptor and, like CPA, long-term therapy is associated with a reduction in cutaneous 5 α -reductase activity.

Different dose schedules of spironolactone have been studied, varying between 50 and 200 mg taken either daily or cyclically (daily for 3 weeks in every 4). A daily dose of 200 mg produces a reduction in subjective hair growth grades of approximately 40% after 6 months of therapy, with little further effect. It is not certain that doses below 200 mg/day are effective at reducing hirsutism.

The main side-effects of spironolactone are breast soreness and menstrual irregularities, but there is considerable variation in their reported incidence. Menstrual irregularities can be eased by the concomitant use of an oral contraceptive containing either CPA or desogestrel as the gestagen.

Finasteride

Finasteride inhibits androgen action by blocking the activity of the type 2 5 α -reductase enzyme. Treatment with finasteride 5 mg daily induces a reduction in hair growth within 3–6 months, as with other antiandrogens. All reported

studies have noted a small, but significant, rise in plasma testosterone during therapy (approximate increase from 1.6 to 2.4 nmol/l). This rise is unexplained and does not appear to be mediated through altered gonadotrophin secretion.

Controlled trials comparing finasteride with other antiandrogens suggest that it is slightly less effective. However, no significant side-effects have been reported.

Flutamide

Flutamide acts as a pure antiandrogen and works by binding to androgen receptors. It appears to have no significant effect on gonadotrophin secretion in women, and therefore androgens do not increase during treatment, unlike the effect in men in whom androgens rise since they regulate gonadotrophin secretion.

Treatment with flutamide 250 mg twice daily, either as a sole agent or in combination with an oral contraceptive, results in reductions in hair scores after 1 year to values considered normal using the Ferriman and Gallwey scale. This therapeutic effect makes flutamide appear the most potent antiandrogen therapy, but flutamide, like all other antiandrogens, has serious hepatotoxic adverse effects (Wallace et al 1993). This adverse effect seems to develop in the first few weeks of therapy, and careful monitoring of liver function is recommended. The incidence of hepatotoxicity in males with prostate cancer is relatively low but fatal cases have occurred. At least one case of hepatic failure requiring liver transplantation has occurred as a direct result of treatment of an hirsute woman.

Other drugs

Corticosteroids

Corticosteroids are first-line therapy for CAH and were the first endocrine therapy to be employed in the treatment of hirsuties with the rationale of suppressing the production of adrenal androgens. It is uncertain how effective they are at reducing androgenic hair growth in hirsute women, and despite subjective impressions of improvement, no objective improvement has been detected (Casey et al 1966). Moreover, glucocorticoids invariably increase insulin resistance and should theoretically worsen the hyperandrogenism.

Ketoconazole

Ketoconazole is a potent inhibitor of adrenal and ovarian steroid synthesis. There have only been isolated reports of its use in hirsuties, but these have demonstrated a marked reduction in hair growth after 6 months. This treatment cannot be recommended in view of the risks of hepatic toxicity during long-term therapy.

Biochemical Monitoring of Androgen-Suppressive Therapy

Therapy for hirsute women is designed to reduce the quantity of hair and it would seem appropriate therefore to measure hair as a means of monitoring therapy. Plasma androgens fall rapidly after initiation of systemic antiandrogen therapy, whereas hair takes several months to fall to a

nadir. Moreover, flutamide, which is the only systemic therapeutic agent reported to reduce hair scores into the 'normal range', does not have any effect on serum testosterone, sex-hormone-binding globulin or gonadotrophins in women.

The need for investigations during therapy should be aimed at monitoring pharmaceutical agents; for example,

liver function tests for CPA, flutamide or ketoconazole, and possibly cortisol for long-term CPA as adrenal failure can rarely occur. All hirsute women should probably be periodically reassessed for glucose intolerance and hyperlipidaemia since they have such an increased risk of developing diabetes.

KEY POINTS

1. Hirsutism is the excessive growth of facial and body hair in a male-pattern distribution.
2. Hirsuties may result from increased androgen production by the ovaries and/or adrenal glands, or increased target-tissue sensitivity to androgens.
3. Virilization involves more severe features of hyperandrogenism including male body habitus, clitoromegaly, balding, voice deepening and increased libido. It is characteristically associated with androgen-producing tumours, CAH or the use of androgenic drugs.
4. The most common cause of hirsutism is polycystic ovary syndrome. Diagnosis is based on ultrasound appearance and/or raised serum testosterone.
5. All women with a serum testosterone that is greater than twice the upper limit of the local laboratory's normal value should be further investigated to exclude CAH or an androgen-secreting tumour. Investigations should include pelvic ultrasound scan, measurement of serum dehydroepiandrosterone and 17α -hydroxyprogesterone and, where indicated, computed tomography or magnetic resonance imaging of the abdomen and pelvis.
6. The diagnosis of idiopathic hirsutism should be limited to those cases in which there is no identifiable pathology to account for the symptoms; the menstrual cycle is regular, the ovaries are normal on ultrasound scan and serum testosterone is less than twice the upper limit of the local laboratory's normal value.
7. A wide variety of cosmetic and medical treatments are available for removing hair. Women with excess facial and body hair should be offered the full spectrum of therapies so that they can choose the most suitable.
8. Weight reduction should be encouraged in overweight and obese women with a body mass index above 25 kg/m^2 prior to starting medical treatment.
9. CPA is the antiandrogen of choice in the management of benign hirsutism, given either in low-dose form as Dianette or at higher doses (25–100 mg) in more severe cases.

Introduction

Premenstrual syndrome (PMS) refers to somatic and psychological symptoms which occur in relation to the luteal phase of the menstrual cycle. Most women of reproductive age will have some symptoms related to the premenstrual phase of the cycle. These are usually very mild and are physiological. Only when the symptoms cause significant disruption to normal functioning are they considered to be PMS. The term 'premenstrual dysphoric disorder' (PMDD) is also used and this represents the severe, predominantly psychological form of PMS. It is estimated that 3–8% of women of reproductive age experience debilitating symptoms leading to functional or psychological impairment (Angst et al 2001, Wittchen et al 2002). PMS and PMDD can be debilitating conditions. The impact on society and women's lives can be very high and comparable to major depressive disorder (Pearlstein et al 2000, Halbriech et al 2003).

Definition

PMS is characterized by symptoms or clusters of symptoms that are associated with the premenstrual phase of the cycle, are recurrent, and are severe enough to cause impairment and distress (Halbriech et al 2007). Any symptom or cluster of symptoms qualify as PMS if they occur during the luteal phase of the menstrual cycle, are alleviated shortly following menses, and are not merely an exacerbation of other underlying conditions. PMDD has similar but separate criteria (Table 27.1, Figures 27.1 and 27.2)

Symptoms

A woman has PMS if she complains of psychological or somatic symptoms, or both, recurring specifically during the

luteal phase of the cycle and resolving by the end of menstruation (Ismail and O'Brien 2005). This separates PMS from psychiatric disorders. The symptoms should be confirmed prospectively by daily ratings during the last two consecutive cycles. This prospective rating is best achieved using the Daily Record of Severity of Problems form (Table 27.2, Box 27.1).

Diagnostic criteria for premenstrual syndrome

An international multidisciplinary group of experts who evaluated the definitions of PMS/PMDD recommended the following diagnostic criteria (Halbriech et al 2007):

- symptom(s) occur up to 2 weeks before menses in most menstrual cycles;
- symptom(s) remit shortly following onset of menses and are absent during most of the midfollicular phase of the menstrual cycle;
- symptom(s) are associated with impairment in daily functioning and/or relationship and/or cause suffering or emotional/physical distress;
- menstrual-related cyclicality, occurrence during the luteal phase and absence during the midfollicular phase are documented by repeated observations by a clinician and/or daily monitoring by the patient (in hysterectomized women, menstrual-related cyclicality is documented by clinical determinations); and
- the symptom(s) are not just an exacerbation or worsening of another mental or physical chronic disorder. PMS may also be a concomitant condition.

Aetiology and Pathophysiology

The precise aetiology of PMS/PMDD is unknown. Various theories have been suggested. The current evidence suggests

Table 27.1 The different types of premenstrual disorders

Type	Definition
Physiological premenstrual symptoms	Symptoms occur in the luteal phase of the cycle but are so mild that they are not troublesome.
Premenstrual syndrome	PMS symptoms leading up to menstruation and completely relieved by the end of menstruation.
Mild	Does not interfere with personal/social and professional life.
Moderate	Interferes with personal/social and professional life but still able to function and interact, maybe suboptimally.
Severe	Unable to interact personally/socially/professionally, withdraws from social and professional activities (treatment resistant).
Premenstrual dysphoric disorder	Currently considered as research criteria, not yet in general use outside the USA, but increasingly addressed in Europe and other countries. This definition of the severe psychological end of the PMS spectrum has been devised by the American Psychiatric Association.
Premenstrual exaggeration	Background psychopathology, physical, medical or other condition which worsens premenstrually with incomplete relief of symptoms when menstruation ends.
Misattribution	Underlying physical, psychological or psychiatric disorder wrongly labelled as PMS by general practitioner, nurse, gynaecologist, other specialist or patient.

Adapted from Royal College Obstetricians and Gynaecologists. Management of Premenstrual Syndrome. Green-top guidelines no. 48. London: RCOG, 2007. Available at: <http://www.rcog.org.uk/womens-health/clinical-guidance/management-premenstrual-syndrome-green-top-48> (Accessed: Feb 2010).

**Figure 27.1** Hypothetical representation of the components of premenstrual syndrome.**Table 27.2** Commonly reported symptoms in women with premenstrual syndrome

Psychological symptoms	Irritability, depression, crying/tearfulness, anxiety, tension, mood swings, lack of concentration, confusion, forgetfulness, unsociableness, restlessness, temper outbursts/anger, sadness/blues, loneliness.
Pain symptoms	Headache/migraine, breast tenderness/soreness/pain/swelling (collectively known as 'premenstrual mastalgia'), back pain, abdominal cramps, general pain.
Bloatedness	Weight gain, abdominal bloating, oedema of extremities (arms and legs), abdominal swelling and water retention.
Appetite symptoms	Increased appetite, food cravings, nausea.
Behavioural symptoms	Fatigue, dizziness, sleep/insomnia, decreased efficiency, accident prone, sexual interest changes, increased energy, tiredness.

Box 27.1 Diagnostic symptoms of premenstrual dysphoric disorder (DSM-IV)

- Markedly depressed mood, feelings of hopelessness or self-deprecating thoughts.
- Marked anxiety, tension or feelings of being 'keyed up or 'on edge'.
- Marked effective liability.
- Persistent and marked anger, irritability or increased interpersonal conflicts.
- Decreased interest in usual activities.
- Subjective sense of difficulty in concentrating.
- Lethargy, easy fatigability or lack of energy.
- Marked changes in appetite.
- Hypersomnia or insomnia.
- Subjective sense of being overwhelmed or out of control.
- Other physical symptoms.

**Figure 27.2** Diagrammatic representation of premenstrual syndrome (PMS) in the population of women of reproductive age. (a) Totally symptom-free women, (b) symptom severity ranges from physiological to moderate PMS, and (c) most severe PMS/premenstrual dysphoric disorder.

the possibility that both ovarian hormonal and neuroendocrine factors contribute to PMS/PMDD. The majority of women of reproductive age experience mild symptoms which are not troublesome and do not interfere with their daily activities. This should be considered as physiological rather than pathological (Figure 27.3).

Ovarian hormones

PMS only occurs in women of reproductive age during the luteal phase of the cycle; symptoms classically disappear when ovulation is absent. PMS is absent before puberty, during pregnancy and following the menopause. Suppression of ovulation with gonadotrophin-releasing hormone (GnRH) analogues (Hussain et al 1992) or following bilateral oophorectomy typically eliminates the symptoms. Conversely, postmenopausal women on sequential combined hormone replacement therapy can redevelop PMS-/PMDD-like symptoms during the progestogen phase of therapy (Hammarback et al 1985).

Previously, it was believed that hormonal or progesterone imbalances during ovulatory cycles may trigger the symptoms. However, administration of progesterone during this phase does not abolish symptoms (Wyatt et al 2001), and differences in oestrogen or progesterone levels have not been demonstrated between PMS patients and asymptomatic controls. Alternative hypotheses include the proposal

that symptoms may be triggered by a preovulatory peak in oestradiol level or a postovulatory increase in progesterone level (Magos et al 1986, Schmidt et al 1998). These hypotheses do not explain why some women only develop symptoms in the late luteal phase.

It remains unclear whether oestrogen or progesterone triggers symptoms. Postmenopausal women on sequential hormone replacement therapy may report mood changes during the progesterone phase of therapy. The symptoms are likely to appear during the days when progesterone dominates over oestrogen, thus the luteal phase in ovulatory cycles.

As there is no clear evidence to implicate different levels of oestrogen or progesterone in inducing PMS, an attractive and convincing theory, partially supported by good evidence, is that an enhanced responsiveness or sensitivity exists to normal levels of these fluctuating hormones (Yonkers et al 2008) (Figures 27.4 and 27.5).

Neuroendocrine systems

Sex steroid receptors are abundant in specific regions of the brain which regulate emotions and behaviour. Serotonin is implicated in regulating mood and behaviour, and serotonin-facilitating drugs are effective as antidepressants and anxiolytic agents. In addition, certain sex steroid hormones exert their effects via serotonergic and γ -amino butyric acid (GABA) neurotransmitter systems.

Figure 27.5 Simulation of premenstrual syndrome (PMS) symptoms on PMS patients after bilateral oophorectomy and hysterectomy. PMS symptoms recur during progesterone treatment but not during unopposed oestrogen.

Adapted from Henshaw et al (1993).

Serotonergic system

Studies undertaken on the rat model demonstrate that serotonin receptor concentrations vary with changes in oestrogen and progesterone levels (Biegen et al 1980). Serotonin depletion affects the sex-steroid-dependent behaviour; this suggests that the role of serotonin is to modulate behavioural changes by interacting with serotonin transmission, which has been demonstrated in studies performed on rodents (Carlsson and Carlsson 1988, Rubinow et al 1998) and non-human primates (Betha et al 2002).

Selective serotonin reuptake inhibitors (SSRIs), serotonin receptor agonists (Landén et al 2001), serotonin precursors (Steinberg et al 1999) and serotonin-enhancing agents effectively dampen premenstrual symptoms. Impairment of serotonin transmission by serotonin receptor antagonists (Roca et al 2002) or a tryptophan-free diet provokes symptoms (Menkes et al 1994). Women with PMS have a low platelet concentration of serotonin and this concentration varies

during the menstrual cycle (Ashby et al 1998). This suggests that serotonin may play an important role in the pathophysiology of PMS/PMDD.

There is limited research on the genetics of serotonin in PMDD, but there does appear to be a difference in specific serotonin receptor polymorphism in PMDD sufferers (Dhingra et al 2007).

The GABAergic system

The GABA transmitter is a major inhibitory system in the central nervous system. GABA levels are low in the plasma and cerebrospinal fluid of individuals with mood disorders (Brambilla et al 2003). GABA levels have also been found to be decreased in women with PMDD during the late luteal phase compared with normal women whose plasma levels increase from the midfollicular phase (Halbriech et al 1996).

Allopregnanolone is a metabolite of progesterone, and levels vary in parallel with progesterone levels during the menstrual cycle (Genazzani et al 1998). In women with PMS, allopregnanolone levels are low in the follicular and luteal phases (Rapkin et al 1997, Bicíková et al 1998). Allopregnanolone is a positive modulator of the GABA receptor and a potent neurotransmitter with effects on mood, behaviour and cognitive function. Allopregnanolone has a bimodal effect on mood symptoms similar to benzodiazepines, barbiturates and alcohol. However, in some women with PMS, the plasma levels of allopregnanolone are low, suggesting that GABA receptor dysfunction might play a role in these women (Girdler et al 2001) (Table 27.3).

Theories related to sodium and fluid retention

Women with PMS report various somatic symptoms in the form of breast tenderness, bloating and swelling. Studies have failed to demonstrate weight gain, changes in abdominal dimensions, or any true water or sodium retention, even in women who experience bloatedness (Faratian et al 1984). There is no evidence to suggest that a shift in premenstrual water and electrolytes occurs; this is paralleled by a lack of similar changes in the hormones which influence potassium and water transport, such as components of atrial natriuretic peptide and the renin–angiotensin system. Studies have consistently shown that evidence is lacking to support this hypothesis.

Prolactin

Prolactin also promotes sodium, potassium and water retention and has direct stimulatory effects on the breast. However, prolactin levels do not undergo change during the menstrual cycle in women with PMS. Women with hyperprolactinaemia do not have symptoms of PMS, and current thinking is that prolactin or changes in prolactin levels are not involved in producing the symptoms of PMS.

Management

The diagnosis should be confirmed before commencing any form of treatment. The importance of a woman's past history is essential. This includes her contraceptive and

Table 27.3 Progesterone and allopregnanolone (progesterone metabolite) levels through the menstrual cycle

Hormone	Day	Premenstrual syndrome	Control
Allopregnanolone	19	6.32 ± 1.35	7.70 ± 1.01
	26	3.60 ± 0.75*	7.51 ± 1.25
Progesterone	19	10.66 ± 0.64	8.88 ± 0.79
	26	7.64 ± 0.91	6.39 ± 0.84
Ratio allopregnanolone: progesterone	19	0.68 ± 0.15	1.17 ± 0.25
	26	0.91 ± 0.26*	3.24 ± 1.25

*Statistically significant.

pregnancy wishes, previous treatment aimed at PMS/PMDD, and history of psychiatric problems, sexual abuse and illicit drug use. These latter conditions may mimic or be confused with PMS/PMDD and thus influence individualized treatment needs.

Non-Pharmacological Treatments

Lifestyle modifications

All women with PMS/PMDD should be advised regarding lifestyle changes before commencing on medications. Although there is no conclusive evidence that these changes improve symptoms of PMS/PMDD, these lifestyle habits will, at least, contribute to overall health and wellbeing. Where possible, important events can be timed to avoid the premenstrual phase. The changes should be initiated during the diagnostic process and continued throughout.

In women with mild-to-moderate symptoms, lifestyle modifications including dietary changes, exercise and cognitive behavioural therapies (CBT) may be enough to improve the symptoms. Dietary modifications in the form of reduced intake of caffeine, salt and refined sugars, a low glycaemic index diet and smaller meals may improve irritability, insomnia, fluid retention, breast tenderness, bloating and weight gain (Rapkin 2003, Kaur et al 2004). Increased intake of complex carbohydrates in the form of drink supplements decreases mood changes; this may be due to an increase in tryptophan, a precursor to serotonin (Sayegh et al 1995, Rapkin 2003). Exercise significantly improves mood and lethargy by increasing the release of endorphins (Aganoff and Boyle 1994). However, the evidence is quite limited for the effectiveness of most of these interventions.

Psychological interventions

These treatments are focused mainly on CBT and include different components. The treatment involves an analysis of triggers and stressors associated with negative emotions, problem solving and relaxation. No major randomized trials are available yet, but series of case studies with good outcomes have been reported.

In one series, women were offered eight sessions of CBT resulting in good outcomes (Slade 1989). Treatment was focused on identification of triggers and stresses associated

with negative emotions, problem solving, relaxation and CBT to clarify attributions to the symptoms. Relaxation therapy was found to be superior to daily PMS symptom monitoring alone, or taking time out to read, in terms of comparative symptomatic approach (Goodale et al 1990). CBT combined with lifestyle changes is more effective in improving mood and PMS symptoms (Christensen AP et al 1995).

One randomized trial compared 10 sessions of CBT with SSRI (fluoxetine 20 mg/day) and both combined (Hunter et al 2002). There was significant improvement in all groups of symptom measures and the percentage of women fulfilling the PMDD criteria post treatment. Both treatments were equally effective at the end of 6 months; however, 1-year follow-up revealed that women who had undergone CBT maintained the improvement compared with women who had been on fluoxetine. Women with depressed mood responded poorly to both treatments, but learning active behavioural coping strategies had a good outcome at 1-year follow-up.

Vitamin or non-medical approaches

Vitamin B6 and pyridoxine

There are no well-designed randomized controlled studies to support the recommendation of any form of vitamin or herbal supplementation. A systematic review of five randomized controlled studies and one intervention study showed limited evidence for vitamin B6 (pyridoxine) supplementation in inadequate studies (Williams et al 2005). Pyridoxine 50–100 mg/day may improve premenstrual depressive symptoms provided that prescribed, daily doses do not exceed 100 mg to avoid the risk of peripheral neuropathy. Due to the poor quality of studies, pyridoxine alone cannot be recommended for treatment, although vitamin B6 and pyridoxine may have some benefit as an adjunct to treat depressive symptoms (pyridoxine is a cofactor necessary for the metabolic conversion of tryptophan to neuropeptides such as serotonin).

Calcium

In a single study, calcium supplementation 600 mg twice daily during the luteal phase of the cycle was shown to

Figure 27.6 Daily Record of Severity of Problems (DRSP). A typical DRSP chart of symptoms for premenstrual syndrome/premenstrual dysphoric disorder sufferer. This shows the range of symptoms, severity of symptoms, luteal phase occurrence, resolution of symptoms with menses and the impact on normal functioning.

Sources: Endicott J, Harrison W: 1990 *Daily Record of Severity of Problems Form*. Department of Research Assessment and Training, New York State Psychiatric Institute, New York. Endicott J, Nee J, Harrison W: 2006 *Archives of Women's Mental Health* 9: 41–49.

reduce emotional and physical symptoms of PMS/PMDD by the second or third treatment cycle (Thys-Jacobs et al 1998).

Agnus castus

A single randomized placebo-controlled study demonstrated that agnus castus (chaste berry) supplementation appeared

to be superior to placebo in relieving irritability, anger, mood swings, headaches and breast fullness (Schellenberg 2001).

Evening primrose oil

Evening primrose oil does appear to be efficacious for cyclical mastalgia.

Box 27.2 Differential diagnoses of PMS**Psychiatric disorders**

- May be confused because of the similarity in symptoms and because of the bipolar and periodic nature of some psychiatric disorders.
- Many women prefer to 'label' their psychological problem as gynaecological rather than psychiatric.
- There are no objective tests but there are many questionnaires. The general health questionnaire (Goldberg Miller 1979) may help to exclude or diagnose psychological ill health. The Daily Record of Severity of Problems form is becoming progressively more accepted as the tool to demonstrate PMS and PMDD.

Intrafamilial and psychosexual problems

- Distinguish between cause and effect.

Other causes of breast symptoms

- Cyclical breast pain may be considered as part of PMS. Can be distinguished from non-cyclical breast disease by history and symptom charts.
- Non-cyclical disease includes severe disorders requiring breast examination and possibly mammography, ultrasonography, aspiration and biopsy.
- Breast cancer must, of course, be excluded.

Other causes of abdominal bloatedness and water retention

- Only a few women exhibit significant water retention in PMS.
- More women have idiopathic oedema which is also cyclical but only occasionally coincides by chance with the menstrual cycle.

- Some women call progressive obesity 'PMS bloatedness'.
- Distinguish by twice-daily weighing.

Endometriosis, pelvic pain and dysmenorrhoea

- Primary dysmenorrhoea occurs with the period.
- Secondary dysmenorrhoea is related to pelvic pathology and may occur premenstrually.
- Laparoscopy will exclude endometriosis and pelvic infection.

Medical causes of lethargy/tiredness and anxiety/irritability

- Occasionally anaemia; haemoglobin estimation advised.
- Rarely hypothyroidism or hyperthyroidism; thyroid function tests will define.

Menopause

- May be confused with PMS in patients over 40 years of age.
- Flushes may occur in PMS; mood change can occur with the menopause.
- Usually distinguished from history.
- Raised follicle-stimulating hormone level can be helpful but not always consistent in the perimenopausal phase.

Other supplements

Supplements such as magnesium, vitamin D and St John's Wort should not be considered as effective treatment options due to a lack of evidence for or against efficacy (Douglas 2002, Kaur et al 2004).

Miscellaneous

Bromocriptine has been advocated in the past; however, in the absence of differences in prolactin levels, it does not seem to be a logical approach but may be beneficial for cyclical mastalgia.

Alternative therapy

Various treatments in the form of massage, biofeedback, acupuncture and reflexology have been proposed but none of these have been proven to be effective. Double-blind randomized and crossover studies for light therapy did not provide conclusive evidence, and there are safety issues to be taken into account before embarking on this form of treatment (Lam et al 1999) (Table 27.4)

Pharmacological Treatments

Patients with mild-to-moderate PMS/PMDD could be offered non-pharmacological treatment options, bearing in mind the limited evidence for their efficacy. In women who do not respond to such treatment and in women with severe

symptoms, pharmacological treatment options should be considered at an earlier stage. The choice of treatment depends on the symptoms and their effect on lifestyle.

Progesterone

The evidence from the meta-analysis and systematic review of 10 randomized controlled trials clearly demonstrates that progesterone is not effective in treating PMS (Wyatt et al 2001). This is not surprising when one considers that progesterone deficiency has never been demonstrated in women with PMS, and when it is appreciated that the administration of sequential hormone replacement therapy to postmenopausal women commonly results in the development of mood changes similar to PMS during the progesterone phase of therapy (Hammarback et al 1985). Progesterone is not recommended in the management of PMS, although progesterone and progestogens are the only licensed products for the management of PMS in the UK (Figure 27.7).

Oestrogen

Oestrogen is effective at suppressing ovulation at doses of 100–200 µg (transdermal patches) (Smith et al 1995, Watson et al 1989). As unopposed oestrogen can cause endometrial hyperplasia and carcinoma, cyclical progestogen should also be administered (Paterson ME et al 1980). Progesterone administration can induce PMS symptoms, thereby limiting the efficacy of oestrogen. In women who are intolerant to cyclical progesterone, a shorter duration of 7 days

Table 27.4 Lifestyle modifications and alternative therapies recommended for use in the treatment of premenstrual syndrome (PMS)/premenstrual dysphoric disorder (PMDD)

Therapy	Dosage (if applicable)	Place in therapy	Level of evidence	Adverse effects/special notes
Calcium	1200 mg/day in divided doses	First-line, adjunctive	B	Nausea, dyspepsia, constipation, renal calculi
Pyridoxine (vitamin B6)	50–100 mg/day	Adjunctive	C	Peripheral neuropathy at high doses(>100 mg/day)
Evening primrose	2–4 g/day	Adjunctive	C	Benefits cyclical mastalgia
Chaste berry (<i>Vitex agnus castus</i>)	20–40 mg/day	Adjunctive	B	Acne, caution use with oral contraceptive pills, hormone replacement therapy, dopamine agonists/antagonist
Diet modification		First-line	C	Should be observed by all women with PMS/PMDD
Light therapy		Adjunctive	B	
Cognitive behavioural therapy (relaxation, sleep hygiene)		Adjunctive	B	
Exercise		First-line	B	
Acupuncture, massage, chiropractice, Reflexology		Adjunctive	B	
Surgery		Last-line; for severe, refractory cases of PMDD	A	Complications, permanent

Source: Jarvis et al (2008). *Annals of Pharmacotherapy* 42: 967–978.

Evidence level A, consistent good-quality, patient-oriented evidence; most studies found similar or coherent conclusions; high-quality systematic reviews and meta-analyses, if they exist, support the recommendation; patient-oriented outcomes that matter to patients, such as morbidity, mortality, symptom improvement, cost reduction and quality of life.

Evidence level B, inconsistent or limited-quality patient-oriented evidence; considerable variation and lack of coherence; high-quality systematic reviews and meta-analyses, if they exist, do not find consistent evidence in favour of recommendation.

Evidence level C, consensus, usual practice, opinion, disease-oriented evidence or case studies; disease-oriented evidence measures intermediate, physiological or surrogate endpoints that may or may not reflect improvements in patient outcomes.

**Figure 27.7** A meta-analysis of trials of progesterone in the management of premenstrual syndrome.

Adapted from Wyatt K, Dimmock P, Jones P, Obhrai M, O'Brien S: 2001 *BMJ (Clinical Research Ed.)* 323: 776–781.

is adequate to prevent endometrial hyperplasia (Studd 2008). A simple regimen is for progestogen to be administered on the first 7 days of each calendar month. A withdrawal bleed occurs on approximately the 10th day of the calendar month.

In women who are intolerant to oral progestogen or who have irregular or heavy bleeding, the levonorgestrel-releasing intrauterine system will usually be beneficial, providing endometrial protection and possibly amenorrhoea without producing PMS-like side-effects (Sitruk-Ware 2007). In some women, levonorgestrel can be absorbed systemically in the first months of therapy until the endometrium becomes atrophic. This is to be expected, and doctors and patients need to be forewarned, particularly of its transient nature.

Oral contraceptive pills

Oral contraceptive pills (OCPs) may be effective in improving physical symptoms such as bloating, headache, abdominal pain and breast tenderness. However, in some women, OCPs may actually worsen the symptoms. Although ovulation is effectively suppressed, exposure to the new exogenous cyclical progestogen may give rise to symptoms, as the mechanism of PMS/PMDD is thought to be the result of PMS patients being progesterone sensitive.

Newer OCPs contain the progestin drospirenone. This is a derivative of spironolactone and has similar antimineralocorticoid and antiandrogenic properties. A systematic review of all randomized controlled trials comparing the combined OCPs containing drospirenone with a placebo or other OCPs for their effect on PMS concluded that drospirenone 3 mg plus ethinyl oestradiol 20 µg may help to treat PMS in women with PMDD (Lopez et al 2008). The drospirenone group had a greater decrease in impairment of productivity, social activities and relationships. Little effect was found on less severe symptoms when comparing drospirenone plus oestrogen with another combined oral contraceptive. A 6-month study showed fewer symptoms with drospirenone, while a 2-year trial found the groups to be similar. Two OCPs, Yaz and Yasmin, containing drospirenone have been approved by the US Food and Drug Administration (FDA) for the treatment of PMDD but are not approved in Europe or the UK. FDA approval gives the manufacturer permission to make claims about the effectiveness of these OCPs for 'treating PMDD in women who require oral contraception'. It highlights the fact that the effectiveness beyond three cycles is unknown.

Danazol

Danazol has been shown to be effective when ovulation is suppressed. However, there are concerns about masculinizing side-effects. At a reduced dose (200 mg) in the luteal phase, danazol has been shown to be effective for cyclical mastalgia but not other symptoms (O'Brien and Abukhalil 1999).

Gonadotropin-releasing hormone agonists

GnRH agonist analogues are the synthetic analogues of naturally occurring GnRH. When administered, they reduce the

secretion of luteinizing hormone and follicle-stimulating hormone, thereby causing anovulation with associated hypo-oestrogenization. GnRH agonists are effective in treating psychological, emotional and physical symptoms associated with ovarian steroid cycles (Brown et al 1994, Freeman et al 1997, Mezrow et al 1994).

Many women do not tolerate the adverse effects, which are in the form of menopausal symptoms including flushes, insomnia, depression, headache and muscle aches. GnRH treatment should normally be limited to no more than 6 months to reduce the risk of reduction in bone mass. There is a likelihood of return of symptoms once the treatment is discontinued. In such women, the duration of therapy may be extended in certain circumstances by the addition of 'add-back' therapy which may be achieved using continuous daily conjugated oestrogen at a dose of 0.625 mg, oestradiol valerate 2 mg or transdermal oestradiol patches 50 µg along with progestogens such as medroxyprogesterone 5–10 mg. 'Add-back' with tibolone is also very useful (Leather et al 1999, Pickersgill 1998). In the small number of women requiring such long-term therapy, bone mineral density evaluation is required and advice on adequate calcium intake should be given (Figure 27.8).

Selective serotonin reuptake inhibitors

Serotonergic neurotransmission plays an important role in the aetiology of PMS/PMDD. Serotonergic antidepressants, particularly SSRIs, have been demonstrated in several placebo-controlled studies to be significantly effective. SSRIs improve emotional and physical symptoms of PMDD, enhance psychosocial function and work performance, and improve quality of life (Pearlstein et al 2000, Wyatt et al 2002, Steiner et al 2006).

SSRIs should be commenced at the lower end of the dosing range and increased according to the response. Significant improvements in irritability, depressed mood and physical symptoms occur during the first menstrual cycle. Women with depressive disorders require at least 6–8 weeks of treatment before any improvement can be demonstrated; it is important to recognize this distinction.

SSRIs can be administered using continuous, intermittent, semi-intermittent or symptom-onset strategies. Women with an irregular menstrual cycle or those who experience intolerable symptoms on discontinuation of treatment will benefit from a continuous daily SSRI dosing regimen. The continuous regimen may also help to improve somatic symptoms associated with PMDD in the long term (Luisi and Pawasauskas 2003).

Intermittent or luteal-phase dosing can be considered in women with adverse side-effects and can be cost-effective. The luteal-phase regimen is initiated on day 14 of the menstrual cycle and is discontinued 1–2 days after the onset of menses. Semi-intermittent treatment involves continuous daily dosing of SSRIs and increasing the dose during the luteal phase. This is ideal for women who experience underlying mood symptoms throughout the cycle with worsening of symptoms during the luteal phase.

SSRIs are well tolerated in the doses used for the treatment of PMDD. Headache, fatigue, insomnia, anxiety and sexual dysfunction are common symptoms associated with the continuous dose regimen (Wyatt et al 2004).

Suppositories

Magill 800 mg
 Freeman (1990) 600 mg
 Corney 400 mg
 Maddocks 400 mg
 Van De Meer 400 mg
 * Vaneslow 200 mg
 Rapkin 200 mg
 Andersch 200 mg

Oral

Freeman (1995) 1760 mg
 Dennerstein 300 mg
 *Vaneslow 300 mg

Overall

* two studies from same trial

Figure 27.8 The effectiveness of gonadotrophin-releasing hormone agonist with and without 'add-back' therapy in treating premenstrual syndrome: a meta analysis.

Adapted from Wyatt et al (2007) BJOG, 111: 585–593.

The US FDA has licensed various SSRIs for PMDD, but they are not licensed in the UK or Europe (Table 27.5).

Other antidepressants

Clomipramine, a tricyclic antidepressant with strong serotonergic activity, may be effective in treating severe PMDD (Sundblad et al 1993). Serotonin-norepinephrine reuptake inhibitors, venlafaxine and duloxetine have been found to be more effective than placebo for the treatment of PMDD (Mazza et al 2008).

Spirolactone

Spirolactone, a potassium-sparing diuretic and aldosterone receptor antagonist, exhibits antimineralocorticoid and antiandrogenic effects and interferes with synthesis of testosterone (Wang et al 1995, Burnet et al 1991). At doses of 25–200 mg/day during the luteal phase, spironolactone can alleviate symptoms of weight gain, bloating and breast tenderness, and may also decrease negative mood and somatic scores despite the fact that there is no evidence of water retention.

Anxiolytic agents

Anxiety is common in PMS/PMDD; anxiolytic agents during the luteal phase of the cycle can be helpful in women with persistent anxiety despite treatment with SSRIs. Alprazolam at a dose of 0.25 mg three to four times per day during the luteal phase has been shown to be effective in double-blind, placebo-controlled trials for the treatment of premenstrual depression, irritability, hostility and social withdrawal (Berger and Presser 1994, Freeman et al 1995).

Surgery

In a small group of women who have not responded or are not able to tolerate the various medical treatments or combinations of medical treatment, surgical management in the form of hysterectomy with bilateral oophorectomy or

bilateral removal of ovaries may be considered (Cronje et al 2004). Obviously, randomized trials are not possible in this form of treatment, but in open studies, 95% of carefully selected women who underwent bilateral oophorectomy and hysterectomy were shown to be very satisfied 4 years after surgery (Cronje et al 2004). These women require long-term hormone replacement therapy in the form of oestradiol; in these circumstances, it is unnecessary to give progesterone. No placebo-controlled studies have been published specifically to demonstrate the efficacy of bilateral oophorectomy alone for the management of PMS/PMDD. When bilateral oophorectomy is contemplated (with or without hysterectomy), most gynaecologists consider that a trial of a GnRH analogue for three cycles is advisable to demonstrate the potential efficacy of what is a very invasive procedure.

Conclusion

Severe PMS/PMDD continues to affect 5% of women of reproductive age. It is very important to establish the diagnosis of this condition using prospective recording Daily Record of Severity of Problems charts and to rule out other diagnoses, particularly anxiety disorders, depression and other conditions which are merely exacerbated during the premenstrual period. The treatment should be individualized according to the specific symptoms of PMS/PMDD. The dietary and lifestyle modifications should be initiated during the diagnostic phase and continued for life; however, the evidence base for these modifications is limited. The use of SSRIs or drospirenone-containing OCPs should be considered as the first line of treatment for many women, and the choice will depend on an individual woman's requirements. Achieving anovulation will effectively eliminate symptoms in the majority of women with severe PMDD, and surgery should be the last option in women who have already failed to respond to any other form of treatment. All women with PMS/PMDD should be counselled carefully, sensitively and in detail prior to treatments being commenced.

Table 27.5 Prescription medications for use in the treatment of premenstrual syndrome (PMS)/premenstrual dysphoric disorder (PMDD). None are licensed for PMS or PMDD in Europe or the UK

Drug class and agents	Dosage	Recommendation for use	Level of evidence	Adverse effects
SSRIs*				
Fluoxetine*	10–20 mg/day (max 60 mg/day)	First-line therapy for somatic and mood symptoms, continuous or intermittent therapy	A	Sexual dysfunction, sleep disturbances (insomnia, sedation, hypersomnia), GI distress, fatigue, headache, nervousness
Sertraline*	50–150 mg/day		A	
Paroxetine	10–30 mg/day		B	
Paroxetine CR	20–30 mg/day		A	
Citalopram	20–30 mg/day		B	
Escitalopram	10–20 mg/day		B	
Other serotonergic antidepressants				
Venlafaxine	50–200 mg/day		B	Sexual dysfunction, insomnia, headache, anorexia nervosa
Duloxetine	60 mg/day		B	Somnolence, dizziness, insomnia, headache, nausea, xerostomia, diarrhoea, constipation
Clomipramine	25–75 mg/day		B	Anticholinergic effects, sexual dysfunction, weight gain
Anxiolytics				
Alprazolam	0.75–1 mg/day (max 4 mg/day)	Second-line therapy for anxiety symptoms, intermittent therapy	B	Drowsiness, sedation, risk of dependence and tolerance
Buspirone	20 mg/day		B	Headache, no risk of dependence or tolerance
Danazol	200 mg/day	Luteal phase for mastalgia	C	Irreversible virilizing effects
GnRH agonists				
Leuprolide	3.75 mg IM every month or 11.25 mg every 3 months	Effective for psychoemotional and physical symptoms; adverse profile and cost limit use; 'add-back therapy' with oestrogen and/or progesterone if used >6 months	B	Hypo-oestrogenic adverse effects including atrophic vaginitis, hot flushes and osteoporosis
Goserelin	3.6 mg SC every month or 10.8 mg SC every 3 months		B	
Nafarelin	200–400 µg intranasally twice daily		B	
Histerilin	10 µg/kg SC daily		B	
Spironolactone	25–200 mg/day during luteal phase	Effective in alleviating breast tenderness and bloating	B	Antioestrogenic effect and hyperkalemia
Oral contraceptive pills				
Ethinyl oestradiol/ drospirenone	Yaz: 20 µg ethinyl oestradiol/3 mg drospirenone daily for 24 days/month. Yasmin: 30 µg ethinyl oestradiol/3 mg drospirenone daily for 21 days/month	Effective in alleviating some PMS symptoms; symptoms may worsen in some women	B	Breast tenderness, nausea, irregular bleeding, thrombosis and hyperkalemia

Source: Jarvis et al (2008). The Annals of Pharmacotherapy 42: 967–978.

CR, controlled release; GI, gastrointestinal; GnRH, gonadotrophin-releasing hormone; SSRI, selective serotonin reuptake inhibitor; SC, subcutaneous; IM, intra muscular.

*Drugs licensed in the USA for PMDD.

KEY POINTS

1. PMS refers to somatic and psychological symptoms which recur in the luteal phase of the menstrual cycle.
2. Most women of reproductive age will have some symptoms related to the premenstrual phase of the cycle. Only when the symptoms cause significant disruption to normal functioning are they considered to be PMS.
3. It is estimated that 3–8% of women of reproductive age experience debilitating symptoms, leading to functional or psychological impairment.
4. PMDD is the severe and predominantly psychological form of PMS.
5. An enormous range of symptoms have been described in PMS. The luteal-phase timing is more important than their character. The symptoms should be confirmed prospectively by daily ratings during the last two consecutive cycles. This prospective rating is best achieved by use of the Daily Record of Severity of Problems form.
6. The current evidence suggests the possibility that both ovarian hormonal and neuroendocrine factors contribute to PMS/PMDD.
7. Ideally, the diagnosis should be confirmed before commencing any form of treatment. Other factors such as contraception need and pregnancy wishes should be considered in the management decision of choice of therapy.
8. In women with mild-to-moderate symptoms, lifestyle modifications including dietary changes, exercise and CBT may be enough to improve the symptoms.
9. Suppression of ovulation using OCPs may be useful. PMS can be reintroduced by progesterone, so the choice of progesterone may be important.
10. GnRH agonists are effective in treating psychological, emotional and physical symptoms associated with ovarian steroid cycles. GnRH treatment should normally be limited to no more than 6 months to reduce the risk of a decrease in bone mass. In certain circumstances, the duration can be extended with the addition of add-back therapy.
11. SSRIs improve the emotional and physical symptoms of PMDD, enhance psychosocial function and work performance, and, in turn, improve quality of life. Their action is immediate and they can, therefore, only be used in the luteal phase.
12. Surgery needs careful consideration. Total abdominal hysterectomy and bilateral oophorectomy should normally be the last option. Women with PMS who undergo hysterectomy for gynaecological pathology reasons in addition to PMS should be offered bilateral oophorectomy at the time of surgery.

Introduction

Increasing life expectancy and decreasing fertility rates mean that the number of older people is projected to grow significantly worldwide. Between 1950 and 2007, the number of people aged 65 years and older increased from 5% to 7% (Population Reference Bureau 2007). Life expectancy at birth in women in countries such as the UK is currently 81 years (World Health Organization 2006). With the menopause occurring in the early 50s, managing the postreproductive period, which extends over several decades, is an increasingly important public health issue.

The Menopause: Definitions and Physiology

The menopause is the cessation of the menstrual cycle and is caused by ovarian failure. The term is derived from the Greek *menos* (month) and *pausos* (ending). The median age at which the menopause occurs is 52 years. The age at menopause is determined by genetic and environmental factors (Gold et al 2001, Elias et al 2003, Reynolds and Obermeyer 2005, Gosden et al 2007). Japanese race and ethnicity may be associated with later age of natural menopause, while Down's syndrome is associated with an early menopause. Growth restriction in late gestation, low weight gain in infancy, starvation in early childhood and smoking may be associated with an earlier menopause. However, being breast fed, higher childhood cognitive ability and increasing parity increase the age of menopause.

Definitions

Various definitions are in use and are detailed below (Utian 1999, World Health Organization 1994).

- *Menopause*: the permanent cessation of menstruation that results from loss of ovarian follicular activity. Natural menopause is recognized to have occurred after 12 consecutive months of amenorrhoea for which no other obvious pathological or physiological cause is present. Menopause occurs with the final menstrual period, and thus is only known with certainty 1 year after the event. No adequate biological marker exists.
- *Perimenopause*: includes the period beginning with the first clinical, biological and endocrinological features of the approaching menopause, such as vasomotor symptoms and menstrual irregularity, and ends 12 months after the final menstrual period.
- *Premenopause*: often used ambiguously to refer to the 1–2 years immediately before the menopause or to the whole of the reproductive period before the menopause. Currently, this term is recommended to be used in the latter sense, encompassing the entire reproductive period from menarche to the final menstrual period.
- *Postmenopause*: from the final menstrual period, regardless of whether the menopause was induced or spontaneous. Surgical menopause is timed precisely but, as noted above, the time of natural menopause

can only be determined retrospectively after a period of 12 months of spontaneous amenorrhoea.

- **Menopausal transition:** the period of time before the final menstrual period, when variability in the menstrual cycle is usually increased.
- **Climacteric:** the phase encompassing the transition from the reproductive state to the non-reproductive state. The menopause itself is a specific event that occurs during the climacteric, just as the menarche is a specific event that occurs during puberty.
- **Climacteric syndrome:** the climacteric is sometimes, but not always, associated with symptoms. When this occurs, the term 'climacteric syndrome' may be used.
- **Induced menopause:** the cessation of menstruation that follows surgical removal of both ovaries or iatrogenic ablation of ovarian function by chemotherapy, radiotherapy or treatment with gonadotrophin-releasing hormone (GnRH) analogues. In the absence of surgery, induced menopause may be permanent or temporary.

Ovarian function and the menopause

Each ovary receives a finite endowment of oocytes, the numbers of which are maximal at 20–28 weeks of intra-uterine life. From mid-gestation onwards, a logarithmic reduction in these germ cells occurs until, approximately 50 years later, the stock of oocytes is depleted (Burger et al 2008). The main steroid hormones produced by the ovary are oestradiol, progesterone and testosterone. Premenopausally, ovarian function is controlled by the two pituitary gonadotrophins: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH is controlled primarily by the pulsatile secretion of hypothalamic GnRH, and is modulated by the negative feedback of oestradiol and progesterone and the ovarian peptide inhibin B. The peptide is a major regulator of FSH secretion and a product of small antral follicles. Its levels respond to the early-follicular-phase increase and decrease in FSH. The age-related decrease in ovarian primordial follicle numbers, which is reflected in a decrease in the number of small antral follicles, leads

to a decrease in inhibin B, which in turn leads to an increase in FSH. LH is principally controlled by GnRH, with negative feedback control from oestradiol and progesterone for most of the cycle; positive oestradiol feedback generates the mid-cycle surge in levels of LH that triggers ovulation.

The ovary gradually becomes less responsive to gonadotrophins several years before menstruation stops, oestrogen levels fall and gonadotrophin levels rise. These changes in circulating levels of hormones frequently occur with ovulatory cycles. As ovarian unresponsiveness becomes more marked, cycles tend to become anovulatory, and complete failure of follicular development eventually occurs. Production of oestradiol is no longer sufficient to stimulate the endometrium, leading to amenorrhoea, with levels of FSH and LH now persistently elevated. Levels of FSH above 30 IU/l are generally considered to be in the postmenopausal range.

The ovaries are also an important source of testosterone, which is hydroxylated to dihydrotestosterone. Testosterone can also be aromatized to oestradiol. Precursor hormones, such as androstenedione and dehydroepiandrosterone (DHEA), are produced in the ovaries and the adrenals, and both possess a less potent androgenic effect than testosterone. By the time women reach their mid-40s, mean circulating levels of testosterone, androstenedione, DHEA and DHEA sulphate are approximately half those of women in their 20s. However, menopausal status does not affect levels of androgens in women aged 45–54 years, and the postmenopausal ovary seems to be an ongoing site of testosterone production.

Stages of reproductive ageing

A staging system that uses the final menstrual period as the anchor to describe reproductive ageing was proposed by the Stages of Reproductive Aging Workshop (STRAW) (Soules et al 2001) (Figure 28.1). This incorporates both menstrual cycle and hormonal parameters. Progression through the STRAW stages is associated with elevations in serum FSH, LH and oestradiol, and decreases in luteal-phase progesterone.

Final Menstrual Period								
Stages:	-5	-4	-3	-2	-1	0	+1	+2
Terminology:	Reproductive			Menopausal transition		Postmenopause		
	Early	Peak	Late	Early	Late*	Early*	Late	
				Perimenopause				
Duration of stage:	Variable			Variable		Ⓐ 1yr	Ⓑ 4yrs	Until demise
Menstrual cycles:	Variable to regular	Regular		Variable cycle length (>7 days different from normal)	≥2 skipped cycles and an interval of amenorrhea (≥60 days)	Amenorrhea x 12 months	None	
Endocrine:	Normal FSH		↑ FSH	↑ FSH			↑ FSH	

*Stages most likely to be characterized by vasomotor symptoms

Figure 28.1 The STRAW reproductive staging system. FSH, follicle-stimulating hormone.

Soules MR, Sherman S, Parrott E, et al. Executive summary: Stages of Reproductive Aging Workshop (STRAW). *Fertil Steril* 2001;76:874–8.

Menopause symptoms

Menopause symptoms include hot flushes and night sweats, depression, tiredness and sexual problems. Symptom reporting varies between cultures (Melby et al 2005). Approximately 70% of women in Western cultures will experience vasomotor symptoms, such as hot flushes and night sweats. However, Japanese women have fewer menopausal complaints than their North American counterparts. Furthermore, rural Mayan women living in the Yucatan, Mexico do not report either hot flushes or night sweats.

Vasomotor symptoms

Flushes are episodes of inappropriate heat loss mediated by cutaneous vasodilation over the upper trunk. Sympathetic nervous control of blood flow in the skin is impaired in women with menopausal flushes, in whom reflex constriction to an ice stimulus cannot be elicited. More recently, serotonin and its receptors in the central nervous system have been implicated. Hot flushes and night sweats may begin before periods stop, and their prevalence is highest in the first year after the final menstrual period. Although they are usually present for less than 5 years, some women will continue to flush beyond the age of 60 years. Although women with a higher level of education seem to have fewer symptoms, evidence about the effect of exercise is conflicting (Daley et al 2007). Current smoking and high body mass index (BMI) may also predispose a woman to more severe or frequent hot flushes (Whiteman et al 2003).

Psychological symptoms

Psychological symptoms include depressed mood, anxiety, irritability, mood swings, lethargy and lack of energy. Transition to menopause confers a higher risk for development of depression, and multiple risk factors such as previous psychological problems and current life stresses appear to increase risk (Frey et al 2008).

Sexual dysfunction

Although women may stay sexually active until their eight or ninth decades of life, sexual problems are common. It has been estimated that they affect approximately one in two women. Interest in sex declines in both sexes with increasing age, and this change is more pronounced in women. The term 'female sexual dysfunction' is now used. An international classification system was elaborated by the International Consensus Development Conference on Female Sexual Dysfunction (Table 28.1) (Basson et al 2000). The most prevalent sexual problems among women are low desire (43%), difficulty with vaginal lubrication (39%) and inability to climax (34%) (Lindau et al 2007).

Chronic Conditions Affecting Postmenopausal Health

These include cardiovascular disease (CVD), osteoporosis, dementia and urinary incontinence.

Table 28.1 Consensus classification system

Classification	Definition
I Sexual desire disorders	
A Hypoactive sexual desire disorder	The persistent or recurrent deficiency (or absence) of sexual fantasies/ thoughts and/or desire for, or receptivity to, sexual activity, which causes personal distress
B Sexual aversion disorder	The persistent or recurrent phobic aversion and avoidance of sexual contact with a sexual partner, which causes personal distress
II Sexual arousal disorders	The persistent or recurrent inability to attain or maintain sufficient sexual excitement, causing personal distress, which may be expressed as a lack of subjective excitement, or genital (lubrication/swelling) or other somatic responses
III Orgasmic disorder	The persistent or recurrent difficulty, delay in or absence of attaining orgasm after sufficient sexual stimulation and arousal, which causes personal distress
IV Sexual pain disorders	
A Dyspareunia	The recurrent or persistent genital pain associated with sexual intercourse
B Vaginismus	The recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina, which interferes with vaginal penetration and causes personal distress
C Non-coital sexual pain disorders	Recurrent or persistent genital pain induced by non-coital sexual stimulation
Adapted from Basson R, Berman J, Burnett A, et al. Report of the international consensus development conference on female sexual dysfunction: definitions and classifications. <i>J Urol</i> 2000;163:888-93. Each of the categories above is subtyped on the basis of the medical history, physical examination and laboratory tests as: (A) lifelong vs acquired; (B) generalized vs situational; or (C) aetiology (organic, psychogenic, mixed or unknown).	

Cardiovascular disease

Worldwide, CVD is the leading cause of death and disability in both sexes. It is the major cause of death in women, accounting for one-third of all deaths. As CVD increases in prevalence with age, and as women live longer than men, more women than men die from CVD each year in many countries. Coronary heart disease (CHD) and stroke are the primary clinical endpoints of CVD. In the UK, approximately half (48%) of all deaths from CVD are from CHD and more than one-quarter (28%) are from stroke. Approximately one in six women die from CHD.

Osteoporosis

Osteoporosis affects one in three women. Osteoporosis is defined in a National Institute of Health Consensus State-

Table 28.2 Definitions of osteoporosis according to the World Health Organization

Description	Definition
Normal	BMD value between -1 SD and $+1$ SD of the young adult mean (T-score -1 to $+1$)
Osteopenia	BMD reduced between -1 and -2.5 SD from the young adult mean (T-score -1 to -2.5)
Osteoporosis	BMD reduced by equal to or more than -2.5 SD from the young adult mean (T score -2.5 or lower)
BMD, bone mineral density; SD, standard deviation.	

ment as 'a skeletal disorder characterized by compromised bone strength predisposing to an increased risk of fracture'. Bone strength reflects the integration of two main features: bone density and bone quality. Bone density is expressed as grams of mineral per area or volume. Bone quality refers to architecture, turnover, damage accumulation (e.g. microfractures) and mineralization. The main clinical manifestations of osteoporosis are fractures of the hip, vertebrae and wrist (Colles' fractures). They have an enormous impact on quality of life, result in significant economic burden and, particularly in the case of hip fractures, are associated with considerable excess mortality. In the year after a hip fracture, mortality is approximately 30%. Approximately 50% of patients who survive a hip fracture have permanent disability and fail to regain their previous level of independence. The number of hip fractures worldwide due to osteoporosis is expected to rise three-fold by the middle of the next century, from 1.7 million in 1990 to 6.3 million by 2050.

Definitions of osteoporosis according to the World Health Organization

The World Health Organization's definitions are based on measurement of bone mineral density (BMD) (Table 28.2). Severe osteoporosis is defined as the presence of a fragility or minimal trauma fracture and low BMD (T-score less than -2.5). The T-score is the number of standard deviations by which the bone in question differs from the young normal mean. Although BMD is a major contributor to risk, other factors, including age, BMI and falls, play a part in determining whether a person will get a fracture. The FRAX tool has been developed by the World Health Organization to evaluate fracture risk (Kanis et al 2008). It is based on individual patient models that integrate the risks associated with clinical risk factors as well as femoral neck BMD. The clinical risk factors comprise BMI (as a continuous variable), a prior history of fracture, a parental history of hip fracture, use of oral glucocorticoids, rheumatoid arthritis and other secondary causes of osteoporosis, current smoking and alcohol intake of 3 or more units/day. The FRAX algorithms give the 10-year probability of hip and other major osteoporotic fractures.

Dementia and cognitive decline

Worldwide, approximately 25 million people have dementia, with 4.6 million new cases of dementia every year (one new case every 7 seconds). It has been estimated that the number of people affected will double every 20 years to 81.1 million by 2040. Dementia is a clinical term used to describe a condition in which there is impairment of cognitive faculties, including loss of memory, language, thinking and judgement, which cause significant difficulties in functioning. A wide variety of disorders can cause dementia; the most common are Alzheimer's disease, vascular dementia and dementia with Lewy bodies.

Dementia causes significant distress to patients, their carers and families, and has an enormous impact on society. While most people with dementia live in the community, they are likely to require residential or nursing home care in the long term.

Urogenital atrophy and urinary incontinence

The lower urinary and genital tracts have a common embryological origin and are approximated closely in adult women. Oestrogen and progesterone receptors are present in the vagina, urethra, bladder and pelvic floor musculature. Urogenital atrophy is common, affecting approximately 25% of women even if they are taking systemic oestrogen replacement. A lack of oestrogen results in the vaginal epithelium becoming thinner, losing its rugae, and becoming pale or erythematous with fine petechial haemorrhages. Vaginal and cervical secretions also decrease, leading to reduced lubrication. The resulting symptoms include dyspareunia, itching, burning and dryness which can coexist with urinary symptoms.

Urinary incontinence affects millions of women throughout the world. It affects the quality of life of women of all ages and poses a large financial burden on society. The population-based prevalence of urinary incontinence in the USA has been estimated to be 45% (Melville et al 2005). Prevalence increased with age, from 28% for women aged 30–39 years to 55% for women aged 80–90 years. Eighteen percent of respondents reported severe urinary incontinence. The prevalence of severe urinary incontinence also increased notably with age, from 8% for women aged 30–39 years to 33% for women aged 80–90 years. Other surveys have reported similar findings.

Therapeutic Options

Oestrogen-based hormone replacement therapy

A wide variety of oestrogen-based preparations are available worldwide, which feature different strengths, combinations and routes of administration (Clinical Knowledge Summaries 2009). Various designations are used: hormone replacement therapy (HRT), hormone therapy, oestrogen therapy, and oestrogen and progestogen therapy for combined preparations (sequential or continuous combined).

Table 28.3 Minimum bone-sparing doses of oestrogen

Oestrogen	Dose
Oestradiol oral	1–2 mg
Oestradiol patch	25–50 µg
Oestradiol gel	1–5 g*
Oestradiol implant	50 mg every 6 months
Conjugated equine oestrogens	0.3–0.625 mg daily
* Depends on preparation.	

HRT consists of an oestrogen, and a progestogen is added in non-hysterectomized women. Progestogens are given cyclically or continuously with the oestrogen.

Oestrogens

Two types of oestrogen are available: natural and synthetic. Natural oestrogens include oestradiol, oestrone and oestriol. Conjugated equine oestrogens contain approximately 50–65% oestrone sulphate, and the remainder consists of equine oestrogens, mainly equilin sulphate. These are also classified as 'natural'. The generally accepted minimum bone-sparing doses of oestrogen are listed in Table 28.3, although increasing evidence shows that even lower doses may be effective. Synthetic oestrogens, such as ethinyl oestradiol used in the combined oral contraceptive pill, are generally considered to be unsuitable for HRT because of their greater metabolic impact, apart for treating young women with premature ovarian failure (POF).

Different routes of administration are employed: oral, transdermal (patches and gels), subcutaneous (implants) and vaginal. The vaginal route is used to treat urogenital symptoms. Vaginal therapies include oestradiol by tablet or ring, or oestriol by cream or pessary. Conjugated equine oestrogen cream is also available but this is well absorbed from the vagina and can cause endometrial stimulation. Systemic absorption with oestradiol vaginal tablets or ring is low, and hormone levels remain within the postmenopausal range. Thus, if the recommended topical oestradiol and oestriol preparations are used, there is no need to add a progestogen for endometrial protection. However, if conjugated equine oestrogens are used on a long-term basis, a progestogen should also be given. Vaginal oestrogens can also be used with systemic oestrogens.

Progestogens

The progestogens used in HRT are almost all synthetic, are structurally different to progesterone and are derived from plant sources. Currently, most are given orally, although norethisterone and levonorgestrel are available in transdermal patches combined with oestradiol, and levonorgestrel can be delivered directly to the uterus. Progesterone itself is available either orally or as a vaginal gel, but availability varies worldwide.

Androgens

Testosterone may be given as patches or as subcutaneous implants to improve libido, but this is not successful in all women, as other factors, such as marital problems, may be involved. Testosterone patches have the advantage of an easily reversible delivery system, as implants cannot be removed easily.

Bioidentical hormones

In some countries, 'natural' or 'bioidentical' hormones are used as an alternative approach. In the USA, the Food and Drug Administration is concerned with the claims for safety, effectiveness and superiority of preparations that are made in compounding pharmacies.

Tibolone

Tibolone is classified as HRT in the UK British National Formulary. Tibolone is a synthetic steroid compound that is itself inert, but, on absorption, is converted *in vivo* to metabolites with oestrogenic, progestogenic and androgenic actions. Tibolone is used in postmenopausal women who wish to have amenorrhoea. It is used to treat vasomotor, psychological and libido problems, and the daily dose is 2.5 mg. Tibolone conserves bone mass and reduces the risk of vertebral and non-vertebral fracture.

Hysterectomized women

In general, hysterectomized women should be given oestrogen alone and have no need for a progestogen. However, in women who have had a subtotal hysterectomy, there may be concern about a remnant of endometrium in the cervical stump. If this is suspected to be the case, the presence or absence of bleeding induced by monthly sequential HRT may be a useful diagnostic test before giving oestrogen alone.

Non-hysterectomized women

Progestogens are added to oestrogens to reduce the increased risk of endometrial hyperplasia and carcinoma that is associated with unopposed oestrogen. Progestogen can be given 'sequentially' for 10–14 days every 4 weeks, for 14 days every 13 weeks, or every day. The first schedule leads to monthly bleeds, the second leads to bleeds every 3 months, and the last aims to achieve amenorrhoea. Progestogen must be given to women who have undergone endometrial ablative techniques or radiotherapy for gynaecological cancer, as it cannot be assumed that all of the endometrium has been destroyed.

Women's Health Initiative and Million Women Study

Publication of the results of the US Women's Health Initiative (WHI) and UK Million Women Study (MWS) since 2002 has led to considerable uncertainties regarding the use

of oestrogen-based HRT (Writing Group for the Women's Health Initiative Investigators 2002, Million Women Study Collaborators 2003, Women's Health Initiative Steering Committee 2004). Several publications have questioned the design, analysis and conclusions of both these studies (Shapiro 2007). For example, in the WHI, women in their 70s were given HRT for the first time, which does not reflect usual clinical practice. In the MWS, it was not easy to control for differences between attendees and non-attendees of the National Health Service Breast Screening Programme and between attendees who agreed or declined to participate in the study. Both studies were undertaken in women aged 50 years and over, and their findings cannot be extrapolated to younger women such as those with premature menopause in their 20s and 30s.

The design of the studies will be described, together with the benefits, risks and uncertainties about oestrogen use in clinical practice.

Women's Health Initiative

The WHI is a large complex series of studies designed in the early 1990s with follow-up until 2010 of strategies for the primary prevention and control of some of the most common causes of morbidity and mortality among healthy postmenopausal women aged 50–79 years. It consisted of a randomized-controlled trial and an observational study. The randomized trial considered not only HRT but also calcium and vitamin D supplementation and a low-fat diet (Box 28.1). If eligible, women could choose to enrol in one, two or all three components of the randomized trial. The randomized trial involved 68,132 women (mean age 63 years): conjugated equine oestrogens (0.625 mg) alone ($n = 10,739$ hysterectomized women), conjugated equine oestrogens (0.625 mg) in combination with medroxyprogesterone acetate (2.5 mg) ($n = 16,608$ non-hysterectomized women), low-fat diet ($n = 48,835$), and calcium and vitamin D supplementation ($n = 36,282$). Women screened for the clinical trial who were ineligible or unwilling to participate in the controlled trial ($n = 93,676$) were recruited into an observational study that assessed new risk indicators and biomarkers for disease.

Million Women Study

The observational MWS examined different HRT regimens, excluding vaginal preparations, in women aged 50–64 years

(mean age 57 years) attending the National Health Service Breast Screening Programme in the UK. In total, 1,084,110 women were recruited between 1996 and 2001; approximately half of these women had ever used HRT. The average duration of follow-up was 2.6 years.

Benefits, risks and uncertainties of oestrogen-based hormone replacement therapy

Benefits

Vasomotor symptoms

There is good evidence from randomized placebo-controlled studies, including the WHI, that oestrogen is effective for the treatment of hot flushes, and improvement is usually noted within 4 weeks (Simon and Snabes 2007). It is more effective than non-hormonal preparations such as clonidine and selective serotonin reuptake inhibitors (see below). The most common indication for HRT prescription is relief of vasomotor symptoms, and it is often used for less than 5 years.

Urogenital symptoms and sexuality

Urogenital symptoms respond well to oestrogen administered either topically or systemically. In contrast to vasomotor symptoms, improvement may take several months. Recurrent urinary tract infections may be prevented by vaginal but not oral oestrogen replacement (Perrotta et al 2008). Topical oestrogens may have a weak effect on urinary urge incontinence, but no improvement of stress incontinence. Long-term treatment is often required as symptoms can recur when therapy is stopped. Sexuality may be improved with oestrogen alone, but testosterone may also be required, especially in young oophorectomized women.

Osteoporosis

There is evidence from randomized-controlled trials (including the WHI) that HRT reduces the risk of both spine and hip fractures, as well as other osteoporotic fractures (Writing Group on Osteoporosis for the British Menopause Society Council 2007). Most epidemiological studies suggest that continuous and lifelong use is required for fracture prevention. However, there is now some evidence that a few years of treatment with HRT around the time of the menopause may have a long-term effect on fracture reduction. While alternatives to HRT use are available for the prevention and treatment of osteoporosis in elderly women (see below), oestrogen still remains the best option, particularly in younger (<60 years) and/or symptomatic women. Few data are available on the efficacy of alternatives such as bisphosphonates in women with POF.

Colorectal cancer

Results from the combined arm, but not the oestrogen-alone arm, of the WHI concur with observational studies that HRT reduces the risk of colorectal cancer. However, little is known regarding the risk of colorectal cancer when treatment is stopped. There is no information about HRT in high-risk populations, and current data do not allow prevention as a recommendation.

Box 28.1 Interventions evaluated by the Women's Health Initiative

- HRT (unopposed and combined): hypothesized to reduce the risk of CHD and other cardiovascular diseases and, secondarily, to reduce the risk of hip and other fractures, with increased risk of breast cancer being studied as a possible adverse outcome.
- Low-fat eating pattern: hypothesized to prevent breast cancer and colorectal cancer and, secondarily, to prevent CHD.
- Supplementation with calcium and vitamin D: hypothesized to prevent hip fractures and, secondarily, to prevent other fractures and colorectal cancer.

Risks

Breast cancer

HRT appears to confer a similar degree of risk as that associated with late natural menopause (2.3% compared with 2.8% per year, respectively). There is no increased risk in HRT users with a premature menopause (Ewertz et al 2005).

The WHI found that:

- combined HRT but not oestrogen-alone HRT increased the risk of breast cancer;
